PACS 72.80.Vp - Electronic transport in graphene

Abstract – The proposals for realizing exotic particles through coupling of quantum Hall effect to superconductivity involve spatially non-uniform magnetic fields. As a step toward that goal, we study, both theoretically and experimentally, a system of Dirac electrons exposed to an Abrikosov flux lattice. We theoretically find that the non-uniform magnetic field causes a carrier-density-dependent reduction of the Hall conductivity. Our studies show that this reduction originates from a rather subtle effect: a levitation of the Berry curvature within Landau levels broadened by the non-uniform magnetic field. Experimentally, we measure the magneto-transport in a monolayer graphene-hexagonal boron nitride-niobium diselenide (NbSe2) heterostructure, and find a density-dependent reduction of the Hall resistivity of graphene as the temperature is lowered from above the superconducting critical temperature of NbSe2, when the magnetic field is uniform, to below, where the magnetic field bunches into an Abrikosov flux lattice.

Introduction. – A promising strategy for creating particles obeying non-Abelian braiding statistics, which may be useful for quantum computation [1], is to integrate superconductivity into the integer quantum Hall (QH) effect, which can produce topological superconductivity (TS) supporting Majorana particles [2–13]. One of the (many) practical challenges toward achieving this goal is that the strong magnetic field required for the QH effect usually kills superconductivity. Even if systems can be found wherein superconductivity survives to sufficiently high magnetic fields, a fundamental difficulty is that a gapped QH state does not couple to a superconductor in a meaningful manner. One can overcome this impediment by considering non-uniform magnetic fields, which produce “dispersive” Landau levels and thus allow, when partially filled, proximity coupling to superconductivity [12,13]. This motivates, as a first step, the need to gain an understanding of the QH effect in the presence of non-uniform magnetic fields. In practice, such non-uniform fields are naturally produced by the nearby superconductor itself, in the form of an Abrikosov flux lattice.

We study, both theoretically and experimentally, a system of Dirac electrons exposed to an Abrikosov flux lattice. Theoretically, we find that non-uniformity of the magnetic field causes a carrier-density-dependent reduction of the Hall conductivity. We explain this reduction qualitatively and semi-quantitatively as a consequence of a rather subtle effect, namely levitation of the Berry curvature within Landau levels broadened by the non-uniform magnetic field. Experimentally, we measure the magneto-transport in a monolayer graphene-hexagonal boron nitride-niobium diselenide (NbSe2) heterostructure, in which the electron and hole gases in graphene are exposed to an Abrikosov flux lattice threading through the NbSe2 layer for temperatures below \( T_c \). We contrast our results with an earlier work [14] below.

Theory. – We consider the model of non-interacting electrons hopping on a lattice subject to an applied magnetic field. Because the Abrikosov vortices themselves form a triangular lattice, it is most natural to consider electrons hopping in a hexagonal lattice, for which we have

(a)Corresponding author.
chosen the honeycomb lattice, which produces Dirac electrons. The Hamiltonian for this model is

$$\hat{H} = -\sum_{(m,n)} t e^{i \theta_{m,n}} c^\dagger_m c_n,$$

(1)

where \(c^\dagger_m\) and \(c_m\) are creation and annihilation operators for electrons at site \(m\), \(t e^{i \theta_{m,n}}\) is the hopping matrix element from site \(n\) to \(m\), the phases \(\theta_{m,n}\) are determined by the local magnetic field up to a gauge transformation, and the sum \((m,n)\) is over nearest neighbor sites. We denote the distance between neighboring sites by \(a\) and quote all lengths in units of \(a\). We choose the magnetic unit cell (MUC) so that the net flux through it is \(\Phi_0 = \hbar/e\). Our choice of periodic gauge is discussed in the Supplementary Material (SM)\(^1\). The energy spectrum of the honeycomb lattice near \(E = 0\) in the uniform magnetic field consists of flat Landau bands, which come in degenerate pairs. This degeneracy is due to the presence of two Dirac cones in the \(B = 0\) spectrum which occur at inequivalent momenta. The spectrum is discussed in more detail in the SM.

Fig. 1: The magnetic flux profile within a magnetic unit cell. The lattice constant of the triangular Abrikosov flux lattice is \(l\). Each flux of size \(d\) is centered on a site and is modeled with the Lorentzian profile of eq. (2).

Our neglect of interaction between electrons is justified for the following reasons. To begin with, we are concerned with high filling factors where correlation effects are not dominant. Further, the main effect of interaction is to renormalize the Fermi velocity of Dirac electrons, to which our results below are not sensitive. Finally, we focus here on the changes that arise when the temperature is reduced from above \(T_c\) to below, and do not expect the effect of interaction to change substantially during this process.

We model the magnetic field of an Abrikosov vortex as

$$B(r) = \frac{C}{r^2 + (d/2)^2}.$$  

(2)

Here \(d\) characterizes the size of the vortex, \(r\) is the distance from the center, and the constant \(C\) is chosen so that the total flux through each vortex (integrated over the MUC) is the superconducting flux quantum \(\Phi_0/2\). The separation between two neighboring vortices will be denoted by \(l\), which is also proportional to the lattice constants of the MUC, as shown in fig. 1. We shall present our results in terms of the dimensionless parameter \(d/l\), and will be interested in the continuum limit, where both \(d\) and \(l\) tend to infinity, with the ratio \(d/l\) held constant.

To calculate the Hall conductivity using the method first described by Thouless et al. [15], one defines the non-Abelian Berry connection, determined by the eigenstates \(|\Psi^\alpha(k)\rangle = e^{ik \cdot r} |u^\alpha(k)\rangle\), as

$$A_\mu^{\alpha\beta}(k) = i \langle u^\beta(k) | \partial_\mu | u^\alpha(k) \rangle,$$

(3)

\(\alpha\) is the shorthand notation for \(\partial/\partial k_\mu\). The Berry curvature \(F\) is then defined as

$$F_{\mu\nu}(k) = \partial_\mu A_\nu - \partial_\nu A_\mu + i [A_\mu, A_\nu].$$  

(4)

The only non-zero components of \(F\) are \(F_{xy} = -F_{yx}\). The Hall conductivity is then given, in units of \(e^2/h\), by the Berry curvature integrated over the Brillouin zone:

$$\sigma_{xy} = \frac{1}{2\pi} \int_{BZ} d^2k \text{Tr} [F_{xy}(k)] \delta (E(k) - E_F),$$

(5)

where the trace is over occupied states. If the Fermi level \(E_F\) lies in a gap, \(\sigma_{xy}\) is given by a topological index called the first Chern number \(C\), which takes integer values. If \(E_F\) lies in a band, the Hall conductivity is no longer an integer. We compute eq. (5) numerically \cite{16}; see SM for details.

For values of \(d/l\) corresponding to the experiment, we find that the computed values of \(\sigma_{xy}\) for non-uniform magnetic fields are less than those for uniform magnetic fields, as shown in fig. 2(a). To quantify the reduction of Hall conductivity, we introduce the quantity

$$\alpha' = \frac{\sigma_{xy}(T < T_c)}{\sigma_{xy}(T > T_c)}.$$  

(6)

The ratio \(\alpha'\) is more natural than \(\alpha\) from the theoretical perspective. As indicated in fig. 2(a), \(\sigma_{xy}\) varies linearly with \(\nu\) for uniform \(B\), as expected, and approximately linearly with \(\nu\) also for non-uniform \(B\) over the \(\nu\) range considered in our calculation (\(\nu \leq 21\)). The reduction increases with decreasing \(d/l\). An earlier calculation \cite{17} of \(\alpha'\) did not evaluate the continuum limit, which, as we see below, significantly alters the results. We also use a more realistic profile for the flux, placing the center of the vortex at a lattice site, as opposed to at the center of a plaquette, which gives a much better convergence to the continuum limit for small \(d/l\). Additionally, we work with Dirac electrons as appropriate for graphene.

An important question is: What is the physical mechanism for the reduction of Hall conductivity in the presence of non-uniform magnetic fields? An obvious possibility

---

\(^1\)The SM presents device characterization, measurement methods, relevance of other possible effects and the role of mesoscopic conductance fluctuations. It also discusses the energy spectrum of the theoretical model, the method by which the phases in the MUC are determined, how the Hall conductivity is computed, the Chern numbers of the Landau bands, and more details about the density dependence of \(\alpha'\).
is that some of the bands (see fig. 2(d)) become trivial, i.e., they have $C = 0$, and thus do not contribute to the Hall conductivity. However, we find in our calculations that all physically relevant degenerate pairs of Landau bands carry shared Chern number $C = 2$ even for the most non-uniform magnetic field that we have considered ($d/l = 0.02$). Certain bands have large and negative $C$ (to ensure that the total Chern number is zero), but these bands occur at relatively high fillings (see SM for further details); we include only bands that are sufficiently far from these bands.

The bands are broadened due to non-uniform $B$, but that also would not cause a correction to $\sigma_{xy}$ so long as the Berry curvature is uniformly distributed in energy. This implies a subtle origin for the reduction of $\sigma_{xy}$, namely a levitation of the Berry curvature within each broadened Landau band. This is corroborated by computation (for degenerate pairs of bands) of the correlation between the Berry curvature $F_{xy}(k)$ and energy $E(k)$, given by

$$\text{corr}(F_{xy}, E) = \frac{1}{\Gamma} \int_{BZ} d^2k (E(k) - \bar{E}) F_{xy}(k),$$

where $\Gamma$ is the bandwidth and $\bar{E}$ is the average energy of the band. We find that this quantity is generally positive (fig. 2(b)), implying that the Berry curvature tends to move away from the low-energy states and concentrate near the high-energy states. When the Fermi energy enters into a band, the low-energy states are occupied first and thus contribute less Berry curvature for non-uniform magnetic $B$.

Because both the magnetic length and size of the Abrikosov fluxes are large compared to the lattice constant for the experimental parameters, we focus on the continuum limit where $l \to \infty$ with $d/l$ constant. The extrapolation of $\alpha'$ to the continuum limit is shown in fig. 2(c), where we have chosen to fit within the filling factor range $0 \leq \nu \leq 21$. The resulting continuum values of $\alpha'$ as a function of $d/l$ are shown by diamonds in fig. 3. We have used the value of $d = 30 \text{nm}$ [18]. The filling factor range $0 \leq \nu \leq 21$ accessible to our theory corresponds to carrier concentration up to $6 \times 10^{19} \text{cm}^{-2}$.

Figure 4 shows the reduction factor $\alpha'$ for $d/l = 0.04$ when fitted up to $\nu_{\text{max}} = 106$; the value $\alpha' = 0.92 \pm 0.04$ is larger than $\alpha' = 0.83 \pm 0.07$ obtained by fitting up to $\nu_{\text{max}} = 21$ (fig. 2(a)). The quantity $\alpha'$ thus depends on the filling factor range available, and, in fact, increases as the filling factor increases, as shown in the inset of fig. 4. We stress that the results shown in the inset are for $l = 30$, and do not represent the continuum limit. The increase in $\alpha'$ can be understood from the observation that the

Fig. 2: (a) The colored curves show the Hall conductivity $\sigma_{xy}$ (in units of $e^2/\hbar$) plotted against filling factor $\nu$ for (from the bottom to top) $d/l = 0.04, 0.08, 0.12, 0.16, 0.2$. All curves begin at $\sigma_{xy} = 0$ but are vertically offset for ease of comparison. The dashed red lines above each colored curve show the Hall conductivity in uniform field. The solid red line is the best linear fit (shown only for $d/l = 0.04$ to avoid clutter), the slope of which gives $\alpha'$. (b) The correlation between the Berry curvature and energy (eq. (7)) for pairs of degenerate bands up to pair 20. The green curve is for $d/l = 0.04$ and the blue curve is form $d/l = 0.2$. The correlation is generally positive for each pair and increases as $d/l$ is made smaller. (c) Continuum limit extrapolations of $\alpha'$ for (from bottom to top) $d/l = 0.02, 0.04, 0.06, \ldots, 0.2$. The lines are linear fits. (d) The LL bands for $d/l = 0.04$ as a function of $k_1$ as viewed along the $k_2$-direction (where $\mathbf{k} = \frac{2\pi}{\Lambda}x - \frac{\pi}{\Lambda}y$, $k_2 = y$ are magnetic reciprocal lattice unit vectors.) The bands at $E = 0$ are flat and not visible in this figure. Whenever the chemical potential lies in a gap between two successive bands, $\sigma_{xy}$ touches its classical values, as seen in panel (a).

Fig. 3: Comparison between experiment and theory for the $d/l$ dependence of $\alpha'$. The theoretical curve is obtained by averaging up to $\nu_{\text{max}} = 21$, which corresponds to a density of $6 \times 10^{19} \text{cm}^{-2}$ ($6 \times 10^6 \text{cm}^{-2}$) for $d/l = 0.2$ ($d/l = 0.02$).
redwction is roughly proportional to the fraction of Landau bands that cross the Fermi energy; this feature vanishes in the limit of very high fillings. This feature of theory is also consistent with the experimental density dependence of \( \alpha' \). We are not able to obtain continuum limit values of \( \alpha' \) for large values of \( \nu_{\text{max}} \), but cannot rule out the possibility that \( \alpha' \rightarrow 1 \) in the limit of very large \( \nu_{\text{max}} \) or large densities (see SM for further details).

**Experiment.** – In this section, we will present our experimental results. Device schematic and measurement setup for the experiment are shown in fig. 5(a). The device consists of graphene/hBN heterostructure on a SiO\(_2\)/Si substrate. The heterostructure was achieved by the standard hot pick-up technique [19]. Contacts were made on graphene in Hall bar geometry using E-beam lithography, and followed by thermal deposition of Cr(5 nm)/Pd (13 nm)/Au (70 nm). A top hBN then covered the device and followed by transfer of a thin NbSe\(_2\) flake (~40 nm) as highlighted in our previous work [20]. The top hBN has a thickness of ~10 nm, which acts as an insulating layer between the graphene channel and the NbSe\(_2\) superconductor. As discussed in the SM, this thickness prevents any proximity induced superconductivity in graphene layer; we have also ruled out shorting between graphene and NbSe\(_2\) from a lack of current between them at room temperature. Standard four-probe measurements are performed using Lock-In amplifier by current biasing the graphene channel and measuring \( V_{\text{xx}} \) (longitudinal voltage) and \( V_{\text{xy}} \) (transverse voltage) simultaneously. The mobility of the graphene was \( \sim 68000 \text{ cm}^2/\text{V s} \). The measurements were done in a He3 cryostat in the temperature \((T)\) range of 250 mK to 15 K. The measured longitudinal \((R_{\text{xx}})\) and Hall resistance \((R_{\text{xy}})\) as a function of the back gate voltage \((V_{\text{BG}})\) at magnetic field 80 mT and temperature 250 mK are shown in fig. 5(b). The \( R_{\text{xx}} \) and \( R_{\text{xy}} \) were measured at several applied magnetic fields in the range from 10 mT to 200 mT. We have measured \( R_{\text{xy}} \) for \(+B\) and \(-B\), then taken averaged \( R_{\text{xy}} \) in order to eliminate the finite contribution coming from the \( R_{\text{xx}} \) component (see SM for details). Similarly, we have measured the \( R_{\text{xx}} \) and \( R_{\text{xy}} \) at several magnetic fields above \( T_c \) (see SM). Figure 5(c) shows the ratio \( \alpha \equiv R_{\text{xy}}(T < T_c)/R_{\text{xy}}(T > T_c) \) as a function of the carrier concentration \((n)\) for 20 mT and 80 mT. In fig. 5(c), the solid lines are the raw data and the dashed linear lines are the linear fittings to obtain the mean value. (d) Mean value of the \( \alpha \) as a function of magnetic field for several values of \( n \). The error bar indicates the standard deviation of the fluctuations of \( \alpha \) in fig. 1(c).
be seen from the SM that for our experiment, $R_{xx} > R_{xy}$, implying $R_{xx}^2 > R_{xy}^2$. As a result, $\alpha_{xy} \propto R_{xy}$. Thus, $\alpha = \sigma_{xy}(T < T_c)/\sigma_{xy}(T > T_c)$ will be very similar to $\alpha = R_{xy}(T < T_c)/R_{xy}(T > T_c)$, as shown by the green line in fig. 3. One can find a qualitative agreement between theoretical and experimental results.

**Discussions.** – One may wonder if other physics might contribute to the reduction of the Hall conductivity, such as hydrodynamic [21] or ballistic effects [22]. As discussed in detail in the SM, these effects are not relevant under the present experimental conditions: the hydrodynamic effects are seen only in extremely clean samples in the intermediate temperature regime (50–150 K) and ballistic effects are seen only in narrow channels [22]. How these effects are modified for non-uniform magnetic fields is an interesting question for future studies. We note that a previous work [14] investigated similar physics but in a different regime. They studied electrons with parabolic dispersion (GaAs-based two-dimensional electron gas), and the locations of the fluxoids in that work were determined mainly by the presence of random disorder in the superconductor. While they also observed a reduction of the Hall resistance, they found that $\alpha$ saturates for very small $d/l$. The origin of this difference is not clear at the moment.

**Conclusions.** – In conclusion, our principal finding is that a non-uniformity in magnetic field causes a levitation of the Berry curvature in broadened Landau levels, which, in turn, results in a reduction of the Hall conductivity, as seen qualitatively by our experiment. Another aspect of our calculations is worth stressing, that the low-lying Landau levels remain surprisingly well defined even for highly non-uniform magnetic fields (see fig. 2(d)), implying that QH effect ought to be observable even when the size of the Abrikosov fluxes is much smaller than their separation. This provides an optimistic outlook for the realization of topological superconductivity by coupling QH effect and superconductivity.
