Abstract

We study the electronic transport through a quantum dot in the Fermi-edge singularity regime, with emphasis on its non-Markovian attributes. These were quantified by the behavior of current noise as well as the trace-distance-based measure of non-Markovianity and found to be pronounced at low temperatures, where the interplay of many-electron correlations and quantum coherence present in the system leads to significant quantum memory effects and non-Markovian dynamics.

1. Introduction

The Fermi-edge singularity (FES) is a phenomenon originating from the interaction of conduction electrons with localized perturbations and is characterized by a power-law divergence. It was first predicted theoretically for x-ray absorption in metals [1] and later verified experimentally [2, 3]. The theory that was then developed [1, 4–7] has been used to describe other situations involving a similar Hamiltonian and leading to the same power-law divergence, such as resonant tunneling through localized levels [8].

The FES in transport through quantum dots (QDs) occurs in the regime where the energy of the localized QD level(s) is comparable to the Fermi energy of one of the leads [8]. The change of occupation in the local level(s) during the tunneling process leads to sudden changes in the scattering potential and, hence, to singular behavior of the current through the QD at resonance and power-law dependence of the current away from resonance [8–12]. As shown in recent experiments [11, 13], current noise at such an FES displays characteristic behavior, including a deep minimum and a slight super-Poissonian peak, which cannot be accounted for by the Markovian theory. The interplay of many-body correlations and quantum coherence is responsible for the large non-Markovian corrections in the FES region [13].

This paper has two objectives: first, we wish to elaborate on the theoretical method used for explaining the experiment in [13] and furthermore, we wish to explicitly demonstrate the presence of quantum memory by using the recently developed measure of the quantum non-Markovianity based on the trace-distance [14, 15]. The paper is organized as follows. In the next section the system under study is introduced, the Hamiltonian governing its evolution is described, including the scattering term that is responsible for the FES behavior, and the equation of motion for the reduced density matrix is formulated. Section 3 contains the formulae for the mean current and non-Markovian noise, as well as the results. These include a comparison between the Markovian and the non-Markovian effects, a description of the parameter dependences of both current and noise and remarks on fitting the experimental data. Finally, section 5 explicitly shows the non-Markovianity of the time evolution by using the trace-distance-based measure of memory. Section 6 then concludes the paper.

2. The system and its equation of motion

The system under study was inspired by the experiments [11, 13] and consists of a QD with a single spin-less level embedded between two leads of non-interacting spin-less electrons, meaning that there is a single channel of transport...
responsible for the current between the emitter and collector leads. This may be easily extended to the spin-full case and/or a multi-level QD and the resulting multi-channel transport. The FES occurs on the emitter lead (referred to as the left lead henceafter) with a much smaller tunneling rate, even at the FES threshold voltage, than the collector (or right) lead, which means that tunneling from the emitter is much less probable than tunneling out of the QD into the collector. The chemical potential of the collector is well below the QD level, while the emitter’s Fermi energy can be tuned in resonance with the left lead. For a schematic diagram of the setup, see figure 1 of [13].

The Hamiltonian of the system is

\[ H = H_{QD} + H_{d0} + H_{LT} + H_{RT} + H_X, \]

where \( H_{QD} \) is the QD Hamiltonian

\[ H_{QD} = \epsilon_0 d^\dagger d, \]

(1)

with \( \epsilon_0 \) denoting the energy of the single level in the QD and \( d^\dagger, d \) being the creation and annihilation operators of an electron in the dot. \( H_{d0} \) with \( \alpha = L, R \) are the Hamiltonians of the left/right leads, respectively,

\[ H_{d\alpha} = \sum_{k_{\alpha}} \epsilon_{k_{\alpha}} c_{k_{\alpha}}^\dagger c_{k_{\alpha}}, \]

(2)

where the creation and annihilation operators for electrons in the left/right leads are denoted by \( c_{k_{\alpha}}^\dagger, c_{k_{\alpha}} \) and the corresponding energies are \( \epsilon_{k_{\alpha}} \). Tunneling from the left lead into the QD and to the right lead is governed by the Hamiltonians \( H_{dT} \) (\( \alpha = L, R \)),

\[ H_{dT} = \sum_{k_{\alpha}} t_{k_{\alpha}} \left( c_{k_{\alpha}}^\dagger d + d^\dagger c_{k_{\alpha}} \right). \]

(3)

Lastly, the FES occurs due to the interaction of the electrons in the left lead with the electron in the QD; this interaction is described by the scattering Hamiltonian \( H_X \),

\[ H_X = \sum_{k_{L}, k_{R}} V_{k_{L}, k_{R}} c_{k_{L}}^\dagger c_{k_{R}} d^\dagger d = V_X d^\dagger d. \]

(4)

In this system, couplings of the left and right leads to the QD state show very different nature and are therefore described by different methods. The right lead is not affected by the FES Hamiltonian, the lead is effectively empty (very low chemical potential) and under the experimentally well-justified assumption of a constant tunnel rate \( \gamma_R = 2\pi \sum_{k_{R}} |t_{k_{R}}|^2 \delta(\epsilon - \epsilon_{k_{R}}) \) (we use units in which \( h = 1 \) throughout this paper) the transport from the QD to the right lead may be treated exactly [16].

This allows us to write the equation of motion for the evolution of the density matrix of the QD and the left lead in a mixed form analogous to the description of charge transport through a Coulomb blockaded double QD in a dissipative environment in [17, 18]. The equation reads as

\[
\frac{d\hat{\sigma}(t)}{dt} = \begin{pmatrix}
0 & \gamma_R & 0 & 0 \\
0 & -\gamma_R & 0 & 0 \\
0 & 0 & -\gamma_R/2 & 0 \\
0 & 0 & 0 & -\gamma_R/2
\end{pmatrix}
\hat{\sigma}(t) - i[H_L, \hat{\sigma}(t)],
\]

(5)

where the first term on the right-hand side describes the effect of the traced-out right lead [16], while the second term accounts for the evolution resulting from the rest of the Hamiltonian, i.e. \( H_L = H_{QD} + H_{d0} + H_{LT} + H_X \). The joint QD and left lead density matrix is written in vector form in terms of the QD states (0) and |1 denote the empty and occupied QDs, respectively \( \hat{\sigma} = (\hat{\sigma}_{00}, \hat{\sigma}_{11}, \hat{\sigma}_{01}, \hat{\sigma}_{10})^T \).

Following closely the procedure of [18], the next step is to divide equation (5) into four equations for the four elements of \( \hat{\sigma} \). Tracing out the electronic states of the left lead in the two equations for the evolution of the diagonal elements \( \hat{\sigma}_{jj} \) (\( j = 0, 1 \)) allows us to find the evolution equations for the QD occupations \( p_0(t) \) (for the empty dot) and \( p_1(t) \) (for an electron in the dot),

\[
\frac{dp_0(t)}{dt} = \frac{dp_1(t)}{dt},
\]

(6)

\[
\frac{dp_0(t)}{dt} = \gamma_R p_1(t) - 2 \sum_{k_{L}} t_{k_{L}} \Im[T_0(c_{k_{L}} \hat{\sigma}_{01}(t))].
\]

The remaining two equations (Hermitian conjugates of each other) govern the evolution of \( \hat{\sigma}_{01} \) (and \( \hat{\sigma}_{10} \)) entering the second of equation (6) and couple to the diagonal elements \( \hat{\sigma}_{jj} \). To close the equations for the QD occupations \( p_j(t) \), we perform physically motivated perturbative decoupling (in relatively small \( t_{k_{L}} \)) of the diagonal elements of the density matrix into \( \hat{\sigma}_{jj}(t) = p_j(t) \otimes \hat{R}_j \), where \( \hat{R}_j = \exp(-[H_{d0} + jV_X - \mu_L \sum_{k_{L}} c_{k_{L}}^\dagger c_{k_{L}}]/k_B T)/Z_j \) are the grand-canonical density matrices of the left lead at equilibrium (described by the chemical potential \( \mu_L \) and temperature \( T \)) when the dot is empty (\( j = 0 \)) or occupied (\( j = 1 \)). Now we find that

\[
\Im\left[T_0(c_{k_{L}} \hat{\sigma}_{01}(t))\right] =
\left[e^{-\frac{\pi i}{2} \gamma_R t} \right] T_0 (e^{i(H_{d0} + V_X) t} c_{k_{L}} e^{-iH_{d0} t} \hat{\sigma}_{01}(0)) \right]
+ \int_0^t \! dt' p_0(t') \Re \left[e^{-\frac{\pi i}{2} \gamma_R (t-t')} \sum_{k_{L}} t_{k_{L}}^* \right] T_0 \left[c_{k_{L}}^\dagger e^{iH_{d0} + V_X (t-t')} c_{k_{L}} e^{-iH_{d0} (t-t')} \hat{R}_{01}(t) \right]
- \int_0^t \! dt' p_1(t') \Re \left[e^{-\frac{\pi i}{2} \gamma_R (t-t')} \sum_{k_{L}} t_{k_{L}}^* \right] T_0 \left[e^{iH_{d0} + V_X (t-t')} c_{k_{L}} e^{-iH_{d0} (t-t')} \hat{R}_{10}(t) \right],
\]

(7)

which, after inserting into equation (6) and substituting \( t' \to t - t' \), leads to the non-Markovian equation of motion for the occupations

\[
\frac{dp_0(t)}{dt} = - \int_0^t \! dt' p_0(t-t') \Re \left[e^{-\frac{\pi i}{2} \gamma_R (t-t')} G_0(t') \right]
+ \gamma_R p_1(t) + \int_0^t \! dt' p_1(t-t') \Re \left[e^{-\frac{\pi i}{2} \gamma_R (t-t')} G_1(t') \right] + \Upsilon(t),
\]
containing the initial-condition-dependent inhomogeneous term
\[ \Upsilon(t) = -2 \sum_{\hat{k}_i} t_{\hat{k}_i} \text{Im} \left[ e^{-\left(\frac{2\delta}{\pi} - i\xi_0\right)t} \text{Tr}_L \left( e^{iH_0 + \nu V_x \delta c_{\hat{k}_i} e^{-i\hat{H}_0 \delta} \hat{\sigma}_0 (0)} \right) \right] \]  
\]
(9)

and the FES Green functions defined as
\[ G_0(t) = \sum_{\hat{k}_i, \hat{k}_e} t_{\hat{k}_i} t_{\hat{k}_e} \text{Tr}_L \left( \hat{c}_{\hat{k}_i} e^{i(H_0 + \nu V_x \delta)} \hat{c}_{\hat{k}_e} e^{-i\hat{H}_0 \delta} \hat{R}_0 \right), \]
\[ G_1(t) = \sum_{\hat{k}_i, \hat{k}_e} t_{\hat{k}_i} t_{\hat{k}_e} \text{Tr}_L \left( e^{i(H_0 + \nu V_x \delta) \hat{c}_{\hat{k}_i} e^{-i\hat{H}_0 \delta} \hat{c}_{\hat{k}_i} ^\dagger \hat{R}_1 \right). \]
\]
(10)

3. Evaluation of the memory kernel

The evaluation of the Green functions (10) is the central topic of the FES theory [4, 5, 7, 19] (for a review, see [6]). The standard procedure is to treat the Green functions in terms of open line \( L_1(t) \) and closed loop \( D_1(t) \) factors, such that
\[ G_j(t) = L_j(t) D_j(t). \]
Following [4], these terms are found to be
\[ D_{0/1}(t) = (\mp \text{i} t \xi_0)^{\alpha \pi/2}, \]
\[ L_0(t) = \sum_{\hat{k}_i} e^{-i\xi_0 \hat{k}_i} t_{\hat{k}_i}^2 \frac{\nu (\xi_0) ^{2\alpha \pi/2}}{\left(\xi_0 - \mu_L \right)^{2\alpha \pi/2}}, \]
\[ L_1(t) = \sum_{\hat{k}_i} e^{-i\xi_0 \hat{k}_i} t_{\hat{k}_i} \frac{\nu (\xi_0) ^{2\alpha \pi/2}}{\left(\xi_0 - \mu_L \right)^{2\alpha \pi/2}}, \]
\]
(11)
with \( \delta \) being the phase shift associated with the scattering effects of the occupied QD level described by \( V_x \) [8], \( \xi_0 \) the ultraviolet cutoff, and \( n_\nu(\epsilon) \) denoting the Fermi–Dirac distribution of the left lead.

At zero temperature, the Fermi distribution reduces to \( n_\nu(\epsilon) = \Theta(\mu_L - \epsilon) \), where \( \Theta(x) \) is the Heaviside step function. This considerably simplifies the problem of finding the functions \( L_j(t) \) and leads to the known time dependence [1, 4] of the zero-temperature FES Green functions
\[ G_{0/1}(t) = \frac{\gamma_0^{\nu}}{2\pi} \xi_0 \Gamma \left(1 - \frac{2\delta}{\pi}\right) e^{-i\mu_L \left(\mp \text{i} t \xi_0\right)^{\alpha \pi - 1}}. \]
\]
(12)
Here, \( \alpha = \frac{2\delta}{\pi} - \frac{\pi}{2} \) is the FES critical exponent (governing the power-law dependence typical of the FES), \( \gamma_0^{\nu} = \frac{2\pi}{\xi_0} \sum_{\hat{k}_i} \left| t_{\hat{k}_i} \right|^2 \delta(\epsilon - \epsilon_0) \) is the non-interacting tunnel rate to the left lead stemming from the Hamiltonian (3), and \( \Gamma(x) \) denotes the Euler gamma function.

Knowing the Green functions, we also know the non-Markovian rates \( \gamma_L^{\nu}(t) = 2 \text{Re} \left[ e^{-\left(\frac{2\delta}{\pi} - i\xi_0\right) \hat{G}_{0/1}(t)} \right] \). Their Laplace transforms needed for the evaluation of the stationary current and noise read as
\[ \gamma_L(z; \Delta) = \frac{\gamma_0^{\nu}}{\pi} \Gamma \left(1 - \frac{2\delta}{\pi}\right) \Gamma(\alpha) \xi_0^{\alpha \pi} \times \text{Im} \left[ \left(\frac{1}{z + \frac{\pi}{2} (1 - i\Delta)}\right)^\alpha \right], \]
\]
(13)

being parametrized by the dimensionless energy-distance from the FES edge \( \Delta = \frac{\mu_L - \epsilon_0}{\pi \xi_0} \).

The finite temperature result is obtained (as shown in [5, 6, 20]) by substituting time \( t \) in equation (12) by the temperature-dependent expression \( \text{Re} \left[ \frac{\sin(\pi \nu t)}{\pi \nu t} \right] \). The tunneling rate in the Laplace space \( \gamma_L(z; \Delta) \) is then equal to
\[ \gamma_L(z; \Delta) = \frac{\gamma_0^{\nu}}{\pi} \Gamma \left(1 - \frac{2\delta}{\pi}\right) \xi_0^{\alpha \pi} \times \text{Im} \left[ \left(\frac{1}{2\pi k_B T} \right)^\alpha \right] \]
\]
(14)
\[ B \left(1 - \frac{\alpha}{2} + \frac{z + \frac{\pi}{2} (1 - i\Delta)}{2\pi k_B T}, \alpha \right). \]

where \( B(x, y) \) is the Beta function. The second equation of equation (13) for the back-flow tunneling rate \( \gamma_L^b(z; \Delta) \) carries over to the finite-temperature case.

The non-Markovian generalized master equation (GME) for QD occupations \( \mathbf{p} = (p^L, p^R) \) stemming from equations (8) and (6) can now be rewritten in the matrix form
\[ \frac{dp(t)}{dt} = \int_0^t d\tau W(t') p(t - \tau) + \Upsilon(t), \]
\]
(15)
with the memory kernel
\[ W(t) = \begin{pmatrix} -\gamma_L(t) & \gamma_R(t) + \gamma_L(t) \\ \gamma_L(t) & -\gamma_L(t) - \gamma_R(t) \end{pmatrix}, \]
\]
(16)
and inhomogeneity \( \Upsilon(t) = \left(\Upsilon(t), -\Upsilon(t)\right)^T \). The explicit form of this initial-condition-dependent term describing the effect of initial correlations in the system is not necessary, as the stationary properties (the mean current and noise) do not depend on it, since it vanishes fast enough for large times. It also drops out from the expression for the trace distance, see below in section 5.

For the evaluation of the current and noise, we need to extend the GME by including the counting field(s) and express it in the Laplace space [17, 18] as
\[ z \mathbf{p}(x, z) - \mathbf{p}(x, t = 0) = W(x, z) \mathbf{p}(x, z) + \Upsilon(x, z), \]
\]
(17)
with the modified kernel (for details of the introduction of the counting fields, see [13, 18])
\[ W(x, z) = \begin{pmatrix} -\gamma_L(z) & \gamma_L(z) e^{-i\xi_0} + \gamma_R e^{i\xi_0} \\ \gamma_L(z) & -\gamma_L(z) - \gamma_R \end{pmatrix}. \]
\]
(18)
4. The current and non-Markovian noise

Following the scheme for calculating zero-frequency cumulants when given the Laplace transformed memory kernel of a generalized master equation described in [17, 18], the mean current and non-Markovian noise in the FES regime can be found. The kernel is given by equation (18) and the resulting stationary current reads as

\[ I(\Delta) = e^{\frac{\gamma_R \gamma_L(0; \Delta)}{\gamma_R + \gamma_L(0; \Delta) + \gamma_L^b(0; \Delta)}}. \]

(19)

The non-Markovian Fano factor is given by

\[ F(\Delta) = 1 - \frac{2\gamma_R \gamma_L(0; \Delta)}{(\gamma_R + \gamma_L(0; \Delta) + \gamma_L^b(0; \Delta))^2} \]

\[ + \frac{2\gamma_R (\gamma_L(0; \Delta) - \gamma_L^b(0; \Delta))}{(\gamma_R + \gamma_L(0; \Delta) + \gamma_L^b(0; \Delta))^2} \gamma_L(0; \Delta), \]

where the prime denotes the \( z \)-derivative at \( z = 0 \), i.e. \( \gamma_L^{(b)}(0; \Delta) = \frac{\partial \gamma_L^{(b)}(z; \Delta)}{\partial z} \bigg|_{z=0} \). The Markovian noise is given by the part of the expression without the derivatives, i.e. the first line of equation (20) only. If, additionally, no back-flow is taken into account \( \gamma_L^b(0; \Delta) \rightarrow 0 \), equation (20) reduces to the widely used Markovian expression [11].

In the following, the parameters \( \alpha = 0.45 \) and \( \gamma_R = 3.4 \times 10^{10} \text{s}^{-1} \) measured in [11] are used, unless explicitly stated otherwise. The \( \alpha \)-dependent prefactor \( \gamma_L^b \Gamma(1 - \frac{2\alpha}{\pi}) e_0^2 / \pi \) can be used to control the height of the current peak; in figures 1–6 it is taken such that \( \gamma_L(0, 0) / \gamma_R = 0.09 \) at zero temperature.

In figure 1 the current and the Fano factor near the FES at zero temperature are depicted as a function of the distance in energy from the singularity, which is represented by the parameter \( \Delta \). Hence, the energy distance is given in units of half of the tunneling rate from the QD into the right (collector) lead. This dimensionless parameter is a more convenient theoretical measure of the energy difference than the applied voltage \( V_{SD} \), since the relationship of the actual change of the energy difference \( \mu_L - \epsilon_0 \) with the change in applied voltage involves a leverage factor \( 13, 21 \) \( \eta = (\mu_L - \epsilon_0)/e(V_{SD} - V_0) \) (where \( V_0 \) is the FES threshold voltage) that is often hard to determine experimentally.

The current shows a typical FES behavior (figure 1(a)), i.e. sharp growth on the low-energy side of the singularity and power-law decay on the high-energy side. In figure 1(b),

![Figure 1](image1.png)

**Figure 1.** (a) The zero-temperature current as a function of \( \Delta \). (b) The non-Markovian (black) and Markovian (red) Fano factors at zero temperature as a function of \( \Delta \).

The Fano factor is plotted for both in the Markovian approximation (red line) and the full non-Markovian result (black line). Comparison of the two curves shows that near the singularity non-Markovian features cannot be neglected, since they change the qualitative and quantitative noise features. Firstly, there is a significant drop in the Fano factor minimum on the high-energy side of the singularity. Secondly, on the low-energy side a new, super-Poissonian peak appears. Both these features can be regarded as signatures of strongly non-Markovian dynamics.

![Figure 2](image2.png)

**Figure 2.** Normalized current (a) and Fano factor (b) at zero temperature as a function of \( \Delta \) for different values of \( \alpha = 0.45 \) (black), 0.35 (blue), 0.55 (red), and 0.65 (orange).

In figure 2 the dependence on the critical exponent. The black curves have been transferred from figure 1, the blue ones correspond to \( \alpha = 0.35 \), the red to \( \alpha = 0.55 \) and the orange to \( \alpha = 0.65 \). The parameters \( \gamma_L^b \) have been adjusted for the three new curves so that the current peaks are of the same height as for the black lines. As expected, the energy dependence of the current on the right side of the singularity changes according to \( I \propto \Delta^{-\alpha} \). As to the Fano factor, for higher critical exponent values the minima are deeper and the curve on its high-energy side is steeper. Varying the critical exponent in the studied range has little effect on the Fano factor on the low-energy side of the singularity.

The dependence on \( \gamma_R \) is shown in figure 3. The black curves have been again transferred from figure 1, while \( \gamma_R \) is halved for the blue curve and doubled for the red curve. The variable \( \Delta \) depends on \( \gamma_R \) itself, so the actual energy changes twice as fast for the black curve and four times as fast for the blue curve with respect to the red curve. As in

![Figure 3](image3.png)

**Figure 3.** The normalized current (a) and Fano factor (b) at zero temperature as a function of \( \Delta \) for different values of \( \gamma_R = \) 3.4 \times 10^{10} \text{s}^{-1} \) (black), 1.7 \times 10^{10} \text{s}^{-1} \) (blue), and 6.8 \times 10^{10} \text{s}^{-1} \) (red). Note that the parameter \( \Delta \) stands for twice the actual energy for the red curve and half for the blue curve with respect to that of the black curve.
Figure 4. The current (a) and Fano factor (b) as a function of \( \Delta \) at different temperatures \( T = 0 \) K (black line), 0.1 K (red), 0.5 K (orange) and 1.0 K (green).

Figure 5. Markovian (red) and non-Markovian (black) Fano factors as a function of \( \Delta \) at 0.1 K (a), 0.5 K (b) and 1.0 K (c).

Figure 2, the parameters \( \gamma_L^0 \) have been adjusted in both cases so that the current peaks are of the same height. For the current, changing the right tunneling rate results primarily in stretching or squeezing of the peak (in energy), while the Fano factor undergoes large variations. Firstly, the minima and maxima are highly \( \gamma_R \) dependent; the dependence is more pronounced than the \( \alpha \) dependence. Secondly, the speed at which the Fano factor approaches unity on the high-energy side of the minima is significantly varied. Contrary to figure 2, the rise on the right side of the minimum is steeper when the minimum is shallower. Both these features are important when fitting experimental data and may serve to check the correctness of the measured right tunneling rate \( \gamma_R \).

The temperature dependence is depicted in figure 4. The current peak is damped and broadened for growing temperatures, as well as blue-shifted, in correspondence with experimental data and theoretical predictions. The features of the Fano factor are also damped, and the super-Poissonian peak disappears at high temperatures. In fact, it is the non-Markovian features becoming less pronounced; they lose any relevance at higher temperatures. This can be seen in figure 5 where the Markovian (red line) and non-Markovian (black line) Fano factors are compared for the same temperatures as in figure 4. The crossover temperature for the irrelevance of non-Markovian corrections depends on system parameters \( \alpha \) and \( \gamma_R \), roughly being of the order of \( \gamma_R \), see section 5.

Finally, let us briefly comment on some consequences of our results for the comparison with experiments. One of the methods used for finding the critical exponent \( \alpha \) relies on collapsing the current curves corresponding to different temperatures to a common curve [10, 12]. This is done by assuming the proportionality

\[
I \propto \text{Im} \left[ \left( \frac{i}{2\pi k_B T} \right)^\alpha B \left[ \frac{1-\alpha}{2} - \frac{\eta(V_{SD} - V_0)e}{2\pi k_B T}, \alpha \right] \right],
\]

(21)

where \( V_{SD} \) is the QD level energy shift, \( V_0 \) is the FES threshold voltage corresponding to the resonance of the QD level with the left leads chemical potential \( \mu_L \), and \( \eta \) is the leverage factor, such that \( \eta(V_{SD} - V_0)e = \Delta_0^2 \). If equation (21) correctly describes the measured \( I-V \) curves, then rescaling the current \( I \rightarrow I_T = IT^\alpha \) and the source–drain voltage \( V_{SD} \rightarrow V_T = (V_{SD} - V_0)e/k_B T \), which lifts any temperature dependence from it,

\[
I_T \propto \text{Im} \left[ \left( \frac{i}{2\pi k_B T} \right)^\alpha B \left[ \frac{1-\alpha}{2} - \frac{i\eta V_T}{2\pi}, \alpha \right] \right],
\]

(22)

will reduce all temperature-dependent curves to one for the correct critical exponent.

Equation (21) is a twofold approximation. Firstly, the current, equation (19), is a nontrivial function of the tunneling rates, for which the proportionality should hold. It reduces to \( I \approx \psi_L(0; \Delta) \) for \( \gamma_R \gg \gamma_L(0; \Delta) \); the theoretical analysis presented in this paper requires this condition to be fulfilled; nonetheless, small deviations of the current from the left tunneling rate should be expected near the singularity.

Secondly and more importantly, comparison of equation (21) with equation (14) shows an additional, real, temperature-dependent factor in the Beta function \( \gamma_R/(4\pi k_B T) \). This factor stems from the first term on the right-hand side of equation (5), which is responsible for the effect of the right lead on the QD. It describes the damping of the coherence of the QD state and is typically neglected. Although this factor is negligible away from the singularity, it plays a significant role in reducing the FES peak. The discrepancy is usually handled by introducing an effective temperature \( k_B T^* = \sqrt{(k_B T)^2 + \Gamma_i^2} \), where the temperature enhancement is wrongly attributed to a nonzero intrinsic linewidth of the QD state \( \Gamma_i \), ascribed to the hybridization of the QD electron state with the emitter (left) lead states.

The current at zero temperature as described by equation (19) is compared with the corresponding curve given by equation (21) at 0 and 0.19K in figure 6. The effective-temperature treatment reproduces the current curves given by equations (19) and (14) at relatively high temperatures; it is then possible to collapse them to a common curve and find the critical exponent \( \alpha \) with reasonable precision (if the leverage factor \( \eta \) is known). The temperature limit of its applicability depends on the critical exponent and the tunneling rate of the right lead \( \gamma_R \) and is of the order of 0.1K. At very low temperatures, collapsing different temperature curves does not yield the correct critical exponent.

5. Direct measure of non-Markovianity of the time evolution

In this section, we address the non-Markovianity of the evolution directly in the time domain using the
recently developed [14] measure of quantum memory based on the trace distance of two initial conditions, which was successfully experimentally tested in a designed quantum-optical experiment [15]. The measure is constructed as follows: first, for any two density matrices \( \rho_{1,2} \) their trace distance is defined as \( D(\rho_1, \rho_2) = \frac{1}{2} \text{Tr} |\rho_1 - \rho_2| \) with \( |A| \equiv \sqrt{A^\dagger A} \). In our case, we only deal with diagonal elements of the density matrix \( \rho = \text{diag}(p_0, p_1) \), which together with the normalization condition \( p_0 + p_1 = 1 \) yields for two probability distributions \( p_{1,2} \)

\[
D(p_1, p_2) = \frac{1}{2} (|p_0^1 - p_0^2|^2 + |p_1^1 - p_1^2|^2) = |p_0^1 - p_0^2|^2 = |\Sigma|.
\]

Now, the measure of non-Markovianity \( \mathcal{N} \) of a dynamical map inducing time evolution (here basically the evolution kernel \( W(t) \), equation (16)) is defined as [14, 15] \( \mathcal{N}(W) = \max_{p_{1,2}, \gamma_R, \gamma_L} \int_{D>0} d\bar{D} D(p_1(t), p_2(t)), \) i.e. the sum of the stretches of distance, where the distance is increasing, maximized over the pairs of initial conditions. The increase in distance is a sign of back-flow of information into the system and is the hallmark of non-Markovian behavior [14].

We can easily find the time evolution of the quantity \( \Sigma(t) \equiv p_0^1(t) - p_0^2(t) \) from equation (15) leading to the expression in the Laplace space

\[
\Sigma(z) = \frac{\Sigma(t = 0)}{z - \gamma_R(z) + \gamma_L(z)} + \frac{\Sigma(t = 0)}{z + \gamma_R(z) + \gamma_L(z)}.
\]

Obviously, \( \Sigma(t) \) (given as the backward Laplace transform of the above expression) is simply proportional to the initial condition \( \Sigma(t = 0) \)—maximization over the initial condition in the measure \( \mathcal{N}(W) \) requires taking its maximum value \( \Sigma(t = 0) = 1 \). The measure uses in its definition the absolute value of \( \Sigma(t) \), which may indeed become negative, in order to ensure the positivity of the distance. A straightforward inspection of the behavior of the distance reveals that the non-Markovianity measure can be obtained in our case by the same prescription applied directly to \( \Sigma \), and in practice, this means that the non-Markovianity measure is basically equal to the depth of the \( \Sigma(t) \)-curve minimum, see figures 7 and 8.

In figure 7 we show the time evolution of \( \Sigma(t) \) at \( \Delta = 0 \) for different values of temperature, while figure 8 depicts the \( \Delta \) dependence at zero temperature. Most importantly, we see that the memory measure is generically nonzero (i.e. there is a finite dip below zero in the curves whose depth gives essentially the memory measure), thus proving by a different method complementary to the noise the existence of quantum memory in the system. In figure 7, we observe an expected monotonic decrease of the non-Markovianity measure with increasing temperature, fully in line with previous findings on noise shown in figure 5. In figure 8 there is, however, a surprising non-monotonic dependence on \( \Delta \); namely, the curve for \( \Delta = 1 \) does not exhibit any minimum and the measure assumes zero value. Moreover, equation (24) contains only a symmetric-in-\( \Delta \) combination of rates and the \( \Sigma(t) \)-curves as well as the memory measure are therefore equal for \( \pm \Delta \), in disagreement with the obvious \( \Delta \)-asymmetry of the Fano factor curves in figure 1(b). This may be caused by the neglect of the off-diagonal matrix elements in our theory for short times (they are irrelevant in

**Figure 6.** The current in the FES regime (black) at zero temperature compared with the approximate current (21) used in scaling at zero effective temperature (blue) and at 0.19 K (red).

**Figure 7.** The memory measure \( \Sigma(t) \) (see the main text for details) as a function of the dimensionless time \( \gamma_R t \) for various values of temperature \( k_B T / \gamma_K = 0 \) (blue), 1/10 (purple; \( T = 0.03 \) K), 1/3 (red; \( T = 0.09 \) K) and 1 (green; \( T = 0.26 \) K) at \( \Delta = 0 \).

**Figure 8.** The memory measure \( \Sigma(t) \) (see the main text for details) as a function of the dimensionless time \( \gamma_R t \) for various values of \( \Delta = 0 \) (blue), 1 (purple), 2 (red) and 3 (green) at zero temperature.
the stationary state and, thus, do not influence the noise). Their proper inclusion (although it is not obvious how to accomplish it) might increase the measure by enlarging the space over which maximization takes place, and potentially also break the symmetry in $\Delta$ which is now present. Despite this issue, the global picture in figure 8, i.e. studying not just a single curve but the whole set of them, clearly reveals the presence of the quantum memory in our system.

6. Conclusion

We have studied the electronic current transport through a QD in the FES regime and have shown that the associated current noise displays pronounced non-Markovian features at low temperatures. This is due to the interplay of many-electron correlations and quantum coherence present in the system, which leads to the significance of quantum memory effects and strongly non-Markovian dynamics. The features include a pronounced deepening of the minimum in the Fano factor on the high-energy side of the singularity and the appearance of a super-Poissonian maximum on the low-energy side.

The study of the current and noise curves parameter dependence shows that although changing the critical exponent and the tunneling rate of the collector (right) lead has similar effects on the current curve, it leads to qualitatively different variations of the Fano factors energy dependence. Hence, noise measurements may be used to check the correctness of the experimentally found values of the critical exponent governing the FES power-law divergence. This is important since there is an ambiguity when fitting the current curves alone (due to problems in establishing the correct leverage factor between energy and applied voltage), and we have also shown that the method of collapsing different-temperature curves to find the critical exponent is approximate and fails at very low temperatures.

Finally, we have checked our noise findings by applying a newly developed measure of quantum non-Markovianity to our problem. The results indeed confirm the presence of quantum memory in the dynamics of the FES transport, although the application of the measure contains a slight inconsistency pointing to the inadequacy of the theoretical description for short times. This could be a topic of further research alongside the obvious task of deriving the governing master equation from a systematic microscopic theory, which is an open nontrivial issue at the moment.
