ABSTRACT

We present libsharp, a code library for spherical harmonic transforms (SHTs), which evolved from the libpsht library and addresses several of its shortcomings, such as adding MPI support for distributed memory systems and SHTs of fields with arbitrary spin, but also supporting new developments in CPU instruction sets like the Advanced Vector Extensions (AVX) or fused multiply-accumulate (FMA) instructions. The library is implemented in portable C++ and provides an interface that can be easily accessed from other programming languages such as C++, Fortran, Python, etc. Generally, libsharp’s performance is at least on par with that of its predecessor; however, significant improvements were made to the algorithms for scalar SHTs, which are roughly twice as fast when using the same CPU capabilities. The library is available at http://sourceforge.net/projects/libsharp/ under the terms of the GNU General Public License.

Key words. methods: numerical – cosmic background radiation – large-scale structure of the Universe

1. Motivation

While the original libpsht library presented by Reinecke (2011) fulfilled most requirements on an implementation of spherical harmonic transforms (SHTs) in the astrophysical context at the time, it still left several points unaddressed. Some of those were already mentioned in the original publication: support for SHTs of arbitrary spins and parallelisation on computers with distributed memory.

Both of these features have been added to libpsht in the meantime, but other, more technical, shortcomings of the library have become obvious since its publication, which could not be fixed within the libpsht framework.

One of these complications is that the library design did not anticipate the rapid evolution of microprocessors during the past few years. While the code supports both traditional scalar arithmetic as well as SSE2 instructions, adding support for the newly released Advanced Vector Extensions (AVX) and fused multiply-accumulate instructions (FMA3/FMA4) would require adding significant amounts of new code to the library, which is inconvenient and very likely to become a maintenance burden in the long run. Using proper abstraction techniques, adding a new set of CPU instructions could be achieved by only very small changes to the code, but the need for this was unfortunately not anticipated when libpsht was written.

Also, several new, highly efficient SHT implementations have been published in the meantime; most notably Wavemoth (Seljebotn 2012) and shtns (Schaeffer 2013). These codes demonstrate that libpsht’s computational core did not make the best possible use of the available CPU resources. Note that Wavemoth is currently an experimental research code not meant for general use.

To address both of these concerns, the library was redesigned from scratch. The internal changes also led to a small loss of functionality; the new code no longer supports multiple simultaneous SHTs of different type (i.e. having different directions or different spins). Simultaneous transforms of identical type are still available, however.

As a fortunate consequence of this slight reduction in functionality, the user interface could be simplified dramatically, which is especially helpful when interfacing the library with other programming languages.

Since backward compatibility is lost, the new name libsharp was chosen for the resulting code, as a shorthand for “Spherical HARmonic Package”.

The decision to develop libsharp instead of simply using shtns was taken for various reasons: shtns does not support spin SHTs or allow MPI parallelisation, it requires more main memory than libsharp, which can be problematic for high-resolution runs, and it relies on the presence of the FFTW library. Also, shtns uses a syntax for expressing SIMD operations, which is currently only supported by the gcc and clang compilers, thereby limiting its portability at least for the vectorised version. Finally, libsharp has support for partial spherical coverage and a wide variety of spherical grids, including Gauss-Legendre, ECP, and HEALPix.

2. Problem definition

This section contains a quick recapitulation of equations presented in Reinecke (2011), for easier reference.

We assume a spherical grid with $N_y$ iso-latitude rings (indexed by $y$). Each of these in turn consists of $N_{x,y}$ pixels (indexed by $x$), which are equally spaced in $\phi$, the azimuth of the first ring pixel being $\varphi_{0,y}$.

A continuous spin-$s$ function defined on the sphere with a spectral band limit of $l_{\text{max}}$ can be represented either as a set of spherical harmonic coefficients $c_{l,m}$, or a set of pixels $p_{x,y}$. These two representations are connected by spherical harmonic synthe-
sis (or backward SHT):
\[ p_{xy} = \sum_{m=-m_{\text{max}}}^{m_{\text{max}}} \sum_{l=0}^{l_{\text{max}}} \hat{s}_{lm} \, i \lambda_{lm}(\theta_y) \exp \left( i m \phi_{0,y} + \frac{2 \pi i m x}{N_{\phi,y}} \right) \]  

(1)

and spherical harmonic analysis (or forward SHT):
\[ \hat{s}_{lm} = \sum_{y=0}^{N_y-1} \sum_{x=0}^{N_x-1} p_{xy} \, w_y \, i \lambda_{lm}(\theta_y) \exp \left( -i m \phi_{0,y} - \frac{2 \pi i m x}{N_{\phi,y}} \right) \]  

(2)

where \( \lambda_{lm}(\theta) := \gamma_{lm}(\theta, 0) \) and \( w_y \) are quadrature weights.

Both transforms can be subdivided into two stages:

\[ p_{xy} = \sum_{m=-m_{\text{max}}}^{m_{\text{max}}} F_{m,y} \exp \left( i m \phi_{0,y} + \frac{2 \pi i m x}{N_{\phi,y}} \right) \]  

(3)

\[ F_{m,y} := \sum_{x=0}^{N_x-1} a_{lm} \, i \lambda_{lm}(\theta_y) \]  

(4)

\[ \hat{s}_{lm} = \sum_{y=0}^{N_y-1} G_{m,y} \, i \lambda_{lm}(\theta_y) \]  

(5)

\[ G_{m,y} := w_y \sum_{x=0}^{N_x-1} p_{xy} \exp \left( -i m \phi_{0,y} - \frac{2 \pi i m x}{N_{\phi,y}} \right) \]  

(6)

Eqs. 3 and 6 can be computed using fast Fourier transforms (FFTs), while Eqs 4 and 5 which represent the bulk of the computational load, are the main target for optimised implementation in libsharp.

3. Technical improvements

3.1. General remarks

As the implementation language for the new library, ISO C99 was chosen. This version of the C language standard is more flexible than the C99 one adopted for libpsht and has gained ubiquitous compiler support by now. Most notably, C99 allows definition of new variables anywhere in the code, which improves readability and eliminates a common source of programming mistakes. It also provides native data types for complex numbers, which allows for a more concise notation in many places. However, special care must be taken not to make use of these data types in the library’s public interface, since this would prevent interoperability with C++ codes (because C++ has a different approach to complex number support). Fortunately, this drawback can be worked around fairly easily.

A new approach was required for dealing with the growing variety of instruction sets for arithmetic operations, such as traditional scalar instructions, SSE2 and AVX. Rewriting the library core for each of these alternatives would be cumbersome and error-prone. Instead we introduced the concept of a generic “vector” type containing a number of double-precision IEEE values and defined a set of abstract operations (basic arithmetics, negation, absolute value, multiply-accumulate, min/max, comparison, masking and blending) for this type. Depending on the concrete instruction set used when compiling the code, these operations are then expressed by means of the appropriate operators and intrinsic function calls. The only constraint on the number of values in the vector type is that it has to be a multiple of the underlying instruction set’s native vector length (1 for scalar arithmetic, 2 for SSE2, 4 for AVX).

3.2. Improved loop structure

After publication of SHT implementations, which perform significantly better than libpsht, especially for \( s = 0 \) transforms (Seljebotn 2012; Schaeffer 2013), it became obvious that some

\[ \text{for } b = \{ \text{all submaps or “blocks”}\} \]
\[ \text{for } m = \{ \emptyset; \text{max}\} \]  

// OpenMP

\[ \text{precompute recursion coefficients} \]
\[ \text{end } l \]
\[ \text{for } y = \{ \text{all rings in submap } b\} \]  

// SSE/AVX

\[ \text{compute } s_{\lambda \beta \gamma}(\theta_y) \]
\[ \text{for } j = \{ \text{all jobs} \} \]
\[ \text{accumulate } F(m, \theta_y, j) \]
\[ \text{end } j \]
\[ \text{end } y \]
\[ \text{end } m \]
\[ \text{end } b \]

Fig. 1. Schematic loop structure of libsharp’s shared-memory synthesis code.

\[ \text{for } b = \{ \text{all submaps or “blocks”}\} \]
\[ \text{for } y = \{ \text{all rings in submap } b\} \]  

// OpenMP

\[ \text{compute } G(m, \theta_y, j) \] using FFT
\[ \text{end } j \]
\[ \text{end } y \]
\[ \text{end } m \]
\[ \text{end } b \]

Fig. 2. Schematic loop structure of libsharp’s shared-memory analysis code.

Using this technique, adding support for new vector instruction sets is straightforward and carries little risk of breaking existing code. As a concrete example, support for the FMA4 instructions present in AMD’s Bulldozer CPUs was added and successfully tested in less than an hour.
bottleneck must be present in libpsht’s approach. This was identified with libpsht’s approach of first computing a whole l-vector of \( \mathcal{A}_{l,m}(\theta) \) in one go, storing it to main memory, and afterwards re-reading it sequentially whenever needed. While the l-vectors are small enough to fit into the CPU’s Level-1 cache, the store and load operations nevertheless caused some latency. For \( s = 0 \) transforms with their comparatively low arithmetic operation count (compared to the amount of memory accesses, this latency could not be hidden behind floating point operations and so resulted in a slow-down. This is the most likely explanation for the observation that libpsht’s \( s = 0 \) SHTs have a much lower FLOP rate compared to those with \( s \neq 0 \).

It is possible to avoid the store/load overhead for the \( \mathcal{A}_{l,m}(\theta) \) by applying each value immediately after it has been computed, and discarding it as soon as it is not needed anymore. This approach is reflected in the loop structure shown in Figs. 1 and 2 which differs from the one in Reinecke (2011) mainly by the fusion of the central loops over \( l \).

In this context another question must be addressed: the loops marked as “SSE/AVX” in both figures are meant to be executed in “blocks”, i.e. by processing several \( y \) indices simultaneously. The block size is equivalent to the size of the generic vector type described in Sect. 5.1. The best value for this parameter depends on hardware characteristics of the underlying computer and therefore cannot be determined a priori. Libsharp always uses a multiple of the system’s natural vector length and estimates the best value by running quick measurements whenever a specific SHT is invoked for the first time. This auto-tuning step approximately takes a tenth of a wall-clock second.

Due to the changed central loop of the SHT implementation, it is no longer straightforward to support multiple simultaneous transforms with differing spins and/or directions, as libpsht did – this would lead to a combinatorial explosion of loop bodies that have to be implemented. Consequently, libsharp, while still supporting simultaneous SHTs, restricts them to have the same spin and direction. Fortunately, this is a very common case in many application scenarios.

3.3. Polar optimisation

As previously mentioned in Reinecke (2011), much CPU time can be saved by simply not computing terms in Eqs. (4) and (5) for which \( \mathcal{A}_{l,m}(\theta) \) is so small that their contribution to the result lies well below the numerical accuracy. Since this situation occurs for rings lying close to the poles and high values of \( m \), referred to as “polar optimisation”.

To determine which terms can be omitted, libsharp uses the approach described in Prézeau & Reinecke (2010). In short, all terms for which

\[
\sqrt{m^2 + s^2} - 2ms \cos \theta - l_{\text{max}} \sin \theta > T
\]

are skipped. The parameter \( T \) is tunable and determines the overall accuracy of the result. Libsharp models it as

\[
T = \max(100, 0.01l_{\text{max}}),
\]

which has been verified to produce results equivalent to those of SHTs without polar optimisation.

4. Added functionality

4.1. SHTs with arbitrary spin

While the most widely used SHTs in cosmology are performed on quantities of spins 0 and 2 (i.e. sky maps of Stokes I and Q/U parameters), there is also a need for transforms at other spins. Lensing computations require SHTs of spin-1 and spin-3 quantities (see, e.g. Lewis 2005). The most important motivation for high-spin SHTs, however, are all-sky convolution codes (e.g. Wandelt & Gorski 2001; Prézeau & Reinecke 2010) and deconvolution map-makers (e.g. Keihanen & Reinecke 2012). The computational cost of these algorithms is dominated by calculating expressions of the form

\[
R_{nl}(\theta) = \sum_{l=\max(|m|,|d|)}^{l_{\text{max}}} a_{nl} b_{ln} d_{nl}(\theta),
\]

where \( a \) and \( b \) denote two sets of spherical harmonic coefficients (typically of the sky and a beam pattern) and \( d \) are the Wigner \( d \) matrix elements. These expressions can be interpreted and solved efficiently as a set of (slightly modified) SHTs with spins ranging from 0 to \( l_{\text{max}} \leq l_{\text{max}} \), which in today’s applications can take on values much higher than 2.

As was discussed in Reinecke (2011), the algorithms used by libpsht for spin-1 and spin-2 SHTs become inefficient and inaccurate for higher spins. To support such transforms in libsharp, another approach was therefore implemented, which is based on the recursion for Wigner \( d \) matrix elements presented in Prézeau & Reinecke (2010).

Generally, the spin-weighted spherical harmonics are related to the Wigner \( d \) matrix elements via

\[
\mathcal{A}_{l,m}(\theta) = (-1)^m \sqrt{\frac{2l+1}{4\pi}} d_{lm}(\theta)
\]

(Goldberg et al. 1967). It is possible to compute the \( d_{lm}(\theta) \) using a three-term recursion in \( l \) very similar to that for the scalar \( Y_{lm}(\theta) \):

\[
\begin{align*}
\cos \theta - \frac{mm'}{l(l+1)} & \quad d_{lm}(\theta) \\
\sqrt{(l-m^2)(l-m'^2)} & \quad d_{l,m+1}(\theta) \\
\sqrt{(l+1)(l+1-m^2)(l+1-m'^2)} & \quad d_{l,m+2}(\theta)
\end{align*}
\]

(Kostelecky & Rockmore 2008). The terms depending only on \( l \), \( m \), and \( m' \) can be re-used for different colatitudes, so that the real cost of a recursion step is two additions and three multiplications.

In contrast to the statements made in McEwen & Wiaux (2011), this recursion is numerically stable when performed in the direction of increasing \( l \); see, e.g. Sect. 5.1.2 for a practical confirmation. It is necessary, however, to use a digital floating-point representation with enhanced exponent range to avoid underflow during the recursion, as is discussed in some detail in Prézeau & Reinecke (2010).

4.2. Distributed memory parallelisation

When considering that, in current research, the required band limit for SHTs practically never exceeds \( l_{\text{max}} = 10^4 \), it seems at first glance unnecessary to provide an implementation supporting multiple nodes. Such SHTs fit easily into the memory of a single typical compute node and are carried out within a few seconds of wall clock time. The need for additional parallelisation becomes apparent, however, as soon as the SHT is no longer considered in isolation, but as a (potentially small) part
for \(m = \{\text{all local } m\}\) \hspace{1cm} // OpenMP
for \(l = \{m; l_{\text{max}}\}\)
  precompute recursion coefficients
end \(l\)
for \(y = \{\text{all rings in the map}\}\) \hspace{1cm} // SSE/AVX
for \(l = \{m; l_{\text{max}}\}\)
  compute \(s_{\text{lambda}}_{lm}(\theta_y, j)\)
  for \(j = \{\text{all jobs}\}\)
    accumulate \(F(m, \theta_y, j)\)
  end \(j\)
end \(y\)
end \(m\)

rearrange \(F(m, \theta_y, j)\) among tasks // MPI

for \(y = \{\text{all local rings}\}\) \hspace{1cm} // OpenMP
for \(j = \{\text{all jobs}\}\)
  compute \(\text{map}(x, y, j)\) using FFT
end \(j\)
end \(y\)

Fig. 4. Schematic loop structure of \textit{libsharp}'s distributed-memory analysis code.

ter is expected to require over 100GB of memory and several hundred CPU cores.

\textit{Libsharp} provides an interface that allows collective execution of SHTs on multiple machines with distributed memory. It makes use of the MPI interface to perform the necessary inter-process communication.

In contrast to the standard, shared-memory algorithms, it is the responsibility of the library user to distribute map data and \(a_{lm}\) over the individual computers in a way that ensures proper load balancing. A very straightforward and reliable way to achieve this is a “round robin” strategy: assuming \(N\) computing nodes, the map is distributed such that node \(i\) hosts the map rings \(i, i+N, i+2N, \text{etc.}\) (and their counterparts on the other hemisphere). Similarly, for the spherical harmonic coefficients, node \(i\) would hold all \(a_{lm}\) for \(m = i, i+N, i+2N, \text{etc.}\). Other efficient distribution strategies do of course exist and may be advantageous, depending on the circumstances under which \textit{libsharp} is called; the library makes no restrictions in this respect.

The SHT algorithm for distributed memory architectures is analogous to the one used in the S'\textsc{h}\textsc{at} package\footnote{\url{http://en.wikipedia.org/wiki/Message_Passing_Interface}} and first published in \cite{Szydlarski2013}; its structure is sketched in Figs. 3 and 4. In addition to the S'\textsc{h}\textsc{at} implementation, the SHT will be broken down into smaller chunks if the average number of map rings per MPI task exceeds a certain threshold. This is analogous to the use of chunks in the scalar and OpenMP-parallel implementations and reduces the memory overhead caused by temporary variables.

It should be noted that \textit{libsharp} supports hybrid MPI and OpenMP parallelisation, which allows, e.g., running an SHT on eight nodes with four CPU cores each, by specifying eight MPI tasks, each of them consisting of four OpenMP threads. In general, OpenMP should be preferred over MPI whenever shared memory is available (i.e. at the computing node level), since the OpenMP algorithms contain dynamic load balancing and have a smaller communication overhead.

4.3. Map synthesis of first derivatives

Generating maps of first derivatives from a set of \(a_{lm}\) is closely related to performing an SHT of spin 1. A specialised SHT mode was added to \textit{libsharp} for this purpose; it takes as input a set of spin-0 \(a_{lm}\) and produces two maps containing \(\partial f/\partial \phi\) and \(\partial f/\partial (\phi \sin \theta)\), respectively.

4.4. Support for additional spherical grids

Direct support for certain classes of spherical grids has been extended in comparison to \textit{libpsht}; these additions are listed below in detail. It must be stressed, however, that \textit{libsharp} can very much as \textit{libpsht} does – perform SHTs on any iso-latitude grid with equidistant pixels on each ring. This very general class of pixelisations includes, e.g., certain types of partial spherical coverage. For these general grids, however, the user is responsible for providing correct quadrature weights when performing a spherical harmonic analysis.

4.4.1. Extended support for ECP grids

\textit{Libpsht} provides explicit support for HEALPix grids, Gauss-Legendre grids, and a subset of equidistant cylindrical projection
(ECP) grids. The latter are limited to an even number of rings at the colatitudes

\[ \theta_n = \frac{(n + 0.5)\pi}{N}, \quad n \in [0; N - 1]. \]  

(12)

The associated quadrature weights are given by Fejér’s first rule \cite{Fejer1933, Gauckler1967}.

Libsharp extends ECP grid support to allow even and odd numbers of rings, as well as the colatitude distributions

\[ \theta_n = \frac{n\pi}{N}, \quad n \in [1; N - 1] \]  

(corresponding to Fejér’s second rule), and

\[ \theta_n = \frac{n\pi}{N}, \quad n \in [0; N] \]  

(corresponding to Clenshaw-Curtis quadrature). This last pixelisation is identical to the one adopted in \cite{Huffenberger2010}. Accurate computation of the quadrature weights for these pixelisations is nontrivial; libsharp adopts the FFT-based approach described in \cite{Waldvogel2006} for this purpose.

4.4.2. Reduced Gauss-Legendre grid

The polar optimisation described in Sect. 4.3 implies that it is possible to reduce the number of pixels per ring below the theoretically required value of \(2l_{\text{max}} + 1\) close to the poles. Eq. (7) can be solved for \(m\) (at a given \(s\), \(l_{\text{max}}\) and \(\theta\)), and using \(2m + 1\) equidistant pixels in the corresponding map results in a pixelisation that can represent a band-limited function up to the desired precision, although it is no longer exact in a mathematical sense. If this number is further increased to the next number composed entirely of small prime factors (2, 3, and 5 are used in libsharp’s case), this has the additional advantage of allowing very efficient FFTs.

Libsharp supports this pixel reduction technique in the form of a thinned-out Gauss-Legendre grid. At moderate to high resolutions (\(l_{\text{max}} > 1000\)), more than 30% of pixels can be saved, which can be significant in various applications.

It should be noted that working with reduced Gauss-Legendre grids, while saving considerable amounts of memory, does not change SHT execution times significantly; all potential savings are already taken into account, for all grids, by libsharp’s implementation of polar optimisation.

4.5. Adjoint and real SHTs

Since Eq. (1) is a linear transform, we can introduce the notation

\[ p = Y a \]  

(15)

for a vector \(a\) of spherical harmonic coefficients and corresponding vector \(p\) of pixels. Similarly, one can write Eq. (2) as

\[ a = Y^T W p, \]  

(16)

where \(W\) is a diagonal matrix of quadrature weights. When including SHTs as operators in linear systems, one will often need the adjoint spherical harmonic synthesis, \(Y^T\), and the adjoint spherical harmonic analysis, \(WY\). For instance, if \(a\) is a random vector with covariance matrix \(C\) in the spherical harmonic domain, then its pixel representation \(Ya\) has the covariance matrix \(YC Y^T\). Multiplication by this matrix requires the use of the adjoint synthesis, which corresponds to analysis with a different choice of weights. Libsharp includes routines for adjoint SHTs, which is more user-friendly than having to compensate for the wrong choice of weights in user code, and also avoids an extra pass over the data.

For linear algebra computations, the vector \(a\) must also include \(a_{0m}\) with \(m < 0\), even if libsharp will only compute the coefficients for \(m \geq 0\). The use of the real spherical harmonics convention is a convenient way to include negative \(m\) without increasing the computational workload by duplicating all coefficients. For the definition we refer to the appendix of \cite{deOliveiraCosta2004}. The convention is supported directly in libsharp, although with a restriction in the storage scheme: The coefficients for \(m < 0\) must be stored in the same locations as the corresponding imaginary parts of the complex coefficients, so that the pattern in memory is \([a_{lm}, a_{-l,-m}]\).

5. Evaluation

Most tests were performed on the SuperMUC Petascale System located at the Leibniz-Rechenzentrum Garching. This system consists of nodes containing 32GB of main memory and 16 Intel Xeon E5-2680 cores running at 2.7 GHz. The exception is the comparison with Wavemoth, which was performed on the Abel cluster at the University of Oslo on very similar hardware: Xeon E5-2670 at 2.6 GHz.

The code was compiled with gcc version 4.7.2. The Intel compiler (version 12.1.6) was also tested, but produced slightly inferior code.

Except where noted otherwise, test calculations were performed using the reduced Gauss-Legendre grid (see Sect. 4.4.2) to represent spherical map data. This was done for the pragmatic purpose of minimising the tests’ memory usage, which allowed going to higher band limits in some cases, as well as to demonstrate the viability of this pixelisation.

The band limits adopted for the tests all obey \(l_{\text{max}} = 2^n - 1\) with \(n \in \mathbb{N}\) (except for those presented in Sect. 5.2.2). This is done in analogy to most other papers on the subject, but leads to some unfamiliar numbers especially at very high \(l_{\text{max}}\).

The number of cores used for any particular run always is a power of 2.

5.1. Accuracy tests

5.1.1. Comparison with other implementations

The numerical equivalence of libsharp’s SHTs to existing implementations was verified by running spherical harmonic synthesis transforms on a Gauss-Legendre grid at \(l_{\text{max}} = 50\) and spins 0, 1, and 2 with both libsharp and Libpsht, and comparing the results. The differences of the results lay well within the expected levels of numerical errors caused by the finite precision of IEEE numbers. Spherical harmonic analysis is implicitly tested by the experiments in the following sections.

5.1.2. Evaluation of SHT pairs

To test the accuracy of libsharp’s transforms, sets of spin=0 \(a_{lm}\) coefficients were generated by setting their real and imaginary parts to numbers drawn from a uniform random distribution in the range [-1:1] (with exception of the imaginary parts for \(m = 0\), which have to be zero for symmetry reasons). This data set was transformed onto a reduced Gauss-Legendre grid and back to spherical harmonic space again, resulting in \(\hat{a}_{lm}\).
The rms and maximum errors of this inverse/forward transform pair can be written as

\[ \varepsilon_{\text{rms}} := \sqrt{\frac{\sum |\hat{a}_{lm} - a_{lm}|^2}{\sum |a_{lm}|^2}} \quad \text{and} \]
\[ \varepsilon_{\text{max}} := \max_{lm} |\hat{a}_{lm} - a_{lm}|. \]

Fig. 5 shows the measured errors for a wide range of band limits. As expected, the numbers are close to the accuracy limit of double precision IEEE numbers for low \( l_{\text{max}} \); rms errors increase roughly linearly with the band limit, while the maximum error seems to exhibit an \( l_{\text{max}}^{3/2} \) scaling. Even at \( l_{\text{max}} = 262143 \) (which is extremely high compared to values typically required in cosmology), the errors are still negligible compared with the uncertainties in the input data in today’s experiments. Analogous experiments were performed for spins 2 and 37, with very similar results (not shown).

### 5.2. Performance tests

Determining reliable execution times for SHTs is nontrivial at low band limits, since intermittent operating system activity can significantly distort the measurement of short time scales. All libsharp timings shown in the following sections were obtained using the following procedure: the SHT pair in question is executed repeatedly until the accumulated wall-clock time exceeds 2 seconds. Then the shortest measured wall-clock time for synthesis and analysis is selected from the available set.

#### 5.2.1. Strong scaling test

To assess strong scaling behaviour (i.e. run time scaling for a given problem with fixed total workload), a spin=2 SHT with \( l_{\text{max}} = 16383 \) was carried out with differing degrees of parallelisation. The accumulated wall-clock time of these transforms (synthesis + analysis) is shown in Fig. 5. It is evident that the scaling is nearly ideal up to 16 cores, which implies that parallelisation overhead is negligible in this range. Beyond 16 cores, MPI communication has to be used for inter-node communication, and this most likely accounts for the sudden jump in accumulated time. At even higher core counts, linear scaling is again reached, although with a poorer proportionality factor than in the intra-node case. Finally, for 1024 and more cores, the communication time dominates the actual computation, and scalability is lost.

#### 5.2.2. Weak scaling test

Weak scaling behaviour of the algorithm is investigated by choosing problem sizes that keep the total work per core constant, in contrast to a fixed total workload. Assuming an SHT complexity of \( O(l_{\text{max}}^3) \), the band limits were derived from the employed number of cores \( N \) via \( l_{\text{max}}(N) = 4096 \cdot N^{1/3} - 1 \). The results are shown in Fig. 6. Ideal scaling corresponds to a horizontal line. Again, the transition from one to several computing nodes degrades performance, whereas scaling on a single node, as well as in the multi-node range, is very good. By keeping the amount of work per core constant, the breakdown of scalability is shifted to 4096 cores, compared with 1024 in the strong scaling test.

It is interesting to note that the scaling within a single node is actually slightly superlinear; this is most likely because in this setup, the amount of memory per core decreases with increasing problem size, which in turn can improve the amount of cache re-use and reduce memory bandwidth per core.

#### 5.2.3. General scaling and efficiency

The preceding two sections did not cover cases with small SHTs. This scenario is interesting, however, since in the limit of small \( l_{\text{max}} \) those components of the SHT implementation with complexities lower than \( O(l_{\text{max}}^3) \) (like the FFT steps of Eqs. 3 and
may begin to dominate execution time. Fig. 8 shows the total wall-clock time for SHT pairs over a very wide range of band limits. For every run the number of cores was chosen sufficiently small to keep parallelisation overhead low.

In analogy to one of the tests described in Reinecke (2011), we computed a lower limit for the number of executed floating-point operations per second in libsharp’s SHTs and compared the result with the theoretical peak performance achievable on the given hardware, which is eight operations per clock cycle (four additions and four multiplications) or 21.6 GFlops/s per core. Fig. 9 shows the results. In contrast to libpsht, which reached approximately 22% for \( s = 0 \) and 43% for \( s = 2 \), both scalar and tensor harmonic transforms exhibit very similar performance levels and almost reach 70% of theoretical peak in the most favourable regime, thanks to the changed structure of the inner loops. For the \( l_{\text{max}} \) range that is typically required in cosmological applications, performance exceeds 50% (even when MPI is used), which is very high for a practically useful algorithm on this kind of computer architecture.

The computation of the \( \ell A_{\ell m}(\theta) \) coefficients accounts for roughly half the arithmetic operations in an SHT. If several SHTs with identical grid geometry and band limit are computed simultaneously, it is possible to re-use these coefficients, thereby reducing the overall operation count. Fig. 10 shows the speed-ups compared to sequential execution for various scenarios, which increase with the number of transforms and reach saturation around a factor of 1.6. This value is lower than the naïvely expected asymptotic factor of 2 (corresponding to avoiding half of the arithmetic operations), since the changed algorithm requires more memory transfers between Level-1 cache and CPU registers and therefore operates at a lower percentage of theoretical peak performance. Nevertheless, running SHTs simultaneously is evidently beneficial and should be used whenever possible.

Especially at high band limits, it is important that the SHT library does not consume a large amount of main memory, to avoid memory exhaustion and subsequent swapping or code crashes. Libsharp is designed with the goal to keep the size of its auxiliary data structures much lower than the combined size of any SHT’s input and output arrays. A measurement is shown...
It must be noted, however, that the measured times do not in-
clude the overhead for auto-tuning and necessary precalcu-
lations, which in the case of shtns are about an order of mag-
nitude more expensive than the SHTs themselves. As a conse-
quence, its performance advantage only pays off if many identi-
cal SHT operations are performed within one run. The origin of
shtns’s performance advantage has not been studied in depth;
however, a quick analysis shows that the measured time differ-
ces scale roughly like \( l_{\text{max}} \), so the following explanations are
likely candidates:

- \( \text{libsharp} \) performs all of its precomputations as part of the
time-measured SHT
- \( \text{libsharp} \)’s flexibility with regard to pixelisation and stor-
age arrangement of input and output data requires some ad-
ditional copy operations
- at low band limits the inferior performance of \( \text{libsharp} \)’s
FFT implementation has a noticeable impact on overall run
times.

The relative performance of both libraries is remarkably in-
sensitive to the number of OpenMP threads; this indicates that
the performance differences are located in parallel code regions
as opposed to sequential ones.

For \( l_{\text{max}} = 16383 \), the time required by the default shtns
autotuner becomes very long (on the order of wall-clock hours),
so that we decided to invoke it with an option for reduced tuning.
It is likely a consequence of this missed optimisation that, at
this band limit, \( \text{libsharp} \) is the better-performing code.

5.2.6. Comparison with existing implementations

Table 1 shows a performance comparison of synthesis/analysis
SHT pairs between \( \text{libsharp} \) and various other SHT implementa-
tions. In addition to the already mentioned shtns, Wave moth,
\(^5\text{S}^3\text{HAT} \) and \( \text{libpsht} \) codes, we also included \( \text{spinsfast} \)
(Haffenberger & Wandelt 2010), \( \text{SSHT} \) (McEwen & Wiaux 2011)
and Glesp (Doroshkevich et al. 2005) in the comparison.

All computations shared a common band limit of 2047 and were
executed on a single core, since the corresponding SHTs are sup-
ported by all libraries and are very likely carried out with a com-
paratively high efficiency by all of them. The large overall num-
ber of possible parameters \( (l_{\text{max}}, \text{spin}, \text{number of simultaneous}
transforms, degree and kind of parallelisation, choice of grid,
etc.) \) prevented a truly comprehensive study.

Overall, \( \text{libsharp} \)’s performance is very satisfactory and
exhibits speed-ups of more than an order of magnitude in sev-
eral cases. The table also demonstrates \( \text{libsharp} \)’s flexibility, since
it supports all of the other codes’ “native” grid geometries,
which is required for direct comparisons.

The three last columns list time ratios measured under dif-
erent assumptions: \( R_{\text{AVX}} \) reflects values that can be expected
on modern (2012 and later) AMD/Intel CPUs supporting AVX,
\( R_{\text{SSE2}} \) applies to older (2001 and later) CPUs with the SSE2 in-
struction set. \( R_{\text{calc}} \) should be used for CPUs from other vendors
like IBM or ARM, since \( \text{libsharp} \) does not yet support vectori-
ation for these architectures.

Fig. 12 shows the relative performance of identical SHT
pairs on a full Gauss-Legendre grid with \( s = 0 \) for \( \text{libsharp} \)
and shtns. For these measurements the benchmarking code deliv-
ered with shtns was adjusted to measure SHT times in a similar
fashion as was described above. The plotted quantity is shtns
wall-clock time divided by \( \text{libsharp} \) wall-clock time for vary-
ing \( l_{\text{max}} \) and number of OpenMP threads. It is evident that shtns
has a significant advantage for small band limits (almost an
order of magnitude) and maintains a slight edge up to \( l_{\text{max}} = 8191 \).
It must be noted, however, that the measured times do not in-
clude the overhead for auto-tuning and necessary precalcu-
lations, which in the case of shtns are about an order of mag-
nitude more expensive than the SHTs themselves. As a conse-
quence, its performance advantage only pays off if many identi-
cal SHT operations are performed within one run. The origin of
shtns’s performance advantage has not been studied in depth;
however, a quick analysis shows that the measured time differ-
ces scale roughly like \( l_{\text{max}} \), so the following explanations are
likely candidates:

- \( \text{libsharp} \) performs all of its precomputations as part of the
time-measured SHT
- \( \text{libsharp} \)’s flexibility with regard to pixelisation and stor-
age arrangement of input and output data requires some ad-
ditional copy operations
- at low band limits the inferior performance of \( \text{libsharp} \)’s
FFT implementation has a noticeable impact on overall run
times.

The relative performance of both libraries is remarkably in-
sensitive to the number of OpenMP threads; this indicates that
the performance differences are located in parallel code regions
as opposed to sequential ones.

For \( l_{\text{max}} = 16383 \), the time required by the default shtns
autotuner becomes very long (on the order of wall-clock hours),
so that we decided to invoke it with an option for reduced tuning.
It is likely a consequence of this missed optimisation that, at
this band limit, \( \text{libsharp} \) is the better-performing code.

6. Conclusions

Judging from the benchmarks presented in the preceding sec-
tion, the goals that were set for the \( \text{libsharp} \) library have been
reached: it exceeds \( \text{libpsht} \) in terms of performance, supports
recent developments in microprocessor technology, allows using
distributed memory systems for a wider range of applications,
and is slightly easier to use. On the developer side, the modular
design of the code makes it much more straightforward to add
support for new instruction sets and other functionality.

In some specific scenarios, especially for SHTs with com-
paratively low band limits, \( \text{libsharp} \) does not provide the best
performance of all available implementations, but given its ex-
treme flexibility concerning grid types and the memory layout
of its input/output data, as well as its compactness (= 8000 lines
of portable and easily maintainable source code without external
dependencies), this compromise certainly seems acceptable.

The library has been successfully integrated into version 3.1
of the HEALPix C++ and Fortran packages. There also exists
an experimental version of the SSHT\(^4\) package with \( \text{libsharp} \)
replacing the library’s original SHT engine. \( \text{libsharp} \) is also used
as SHT engine in an upcoming version of the Python pack-
ge (\( \text{NIFT} \))\(^5\) for signal inference (Selig et al. 2013). Recently,
the total convolution code \( \text{convqt} \) (Prézeau & Reinecke 2010),
which is a central component of the \textit{Planck} simulation pipeline
(Reinecke et al. 2006), has been updated and is now based on
\( \text{libsharp} \) SHTs. There are plans for a similar update of the
\texttt{arcDeco} deconvolution map maker (Keihänen & Reinecke
2012).

A potential future field of work is porting \( \text{libsharp} \) to Intel’s “many integrated cores” architecture\(^3\) once sufficient
compiler support for this platform has been established. The

|               |         |                     | 2    | 1                     | 13.40                | 9.29                 | 4.99                 |
|               |         |                     | 2    | 5                     | 6.80                 | 4.66                 | 2.56                 |
| Glesp         | 2       | Gauss-Legendre      | 0    | 1                     | 55.32                | 31.26                | 14.95                |

Notes. All tests had a band limit of \( l_{\text{max}} = 2047 \) and were carried out on a single core. The grids used by libsharp and the respective comparison code were identical in each run. \( R_{\text{AVX}} \) denotes the quotient of wall-clock times for the respective code and libsharp in the presence of the AVX instruction set, \( R_{\text{SSE2}} \) is the quotient when SSE2 (but not AVX) is supported, and \( R_{\text{scalar}} \) was measured with both SSE2 and AVX disabled. The libsharp support for the MW sampling theorem used for the SSHT comparisons is experimental. For Wavemoth, butterfly matrix compression can optionally be enabled. In the benchmark given we requested an accuracy of \( 10^{-4} \), which led to an extra requirement of 4 GB of precomputed data in memory. Note that when running on a single core, Wavemoth is at an advantage compared to the normal situation where the memory bus is shared between multiple cores.

hardware appears to be very well suited for running SHTs, and the porting by itself would provide a welcome test for the adaptability of the library’s code design.

Acknowledgements. We thank our referee Nathanael Schaeffer for his constructive remarks and especially for pointing out a missed optimisation opportunity in our shtns installation, which had a significant effect on some benchmark results. MR is supported by the German Aeronautics Center and Space Agency (DLR), under program 50-OP-0901, funded by the Federal Ministry of Economics and Technology. DSS is supported by the European Research Council, grant StG2010-257080. The presented benchmarks were performed as project pr89yi at the Leibniz Computing Center Garching.
