Radiative and mechanical feedback of massive stars regulates star formation and galaxy evolution. Positive feedback triggers the creation of new stars by collecting dense shells of gas, while negative feedback disrupts star formation by shredding molecular clouds. Although key to understanding star formation, their relative importance is unknown. Here, we report velocity-resolved observations from the SOFIA (Stratospheric Observatory for Infrared Astronomy) legacy program FEEDBACK of the massive star-forming region RCW 120 in the [CII] 1.9-THz fine-structure line, revealing a gas shell expanding at 15 km/s. Complementary APEX (Atacama Pathfinder Experiment) CO J = 3-2 345-GHz observations exhibit a ring structure of molecular gas, fragmented into clumps that are actively forming stars. Our observations demonstrate that triggered star formation can occur on much shorter time scales than hitherto thought (<0.15 million years), suggesting that positive feedback operates on short time periods.

INTRODUCTION

Radiative and mechanical feedback by massive stars on their nascent clouds is thought to play a key role in limiting the star formation efficiency of molecular clouds ("negative feedback"). This controls the evolution of galaxies (1–3). Photo-ionization by ultraviolet photons will set up evaporative ionized gas flows, removing material from these clouds (4). Massive stars also have powerful winds that efficiently remove material from molecular clouds (5–8). Both processes often create a bubble geometry, with the formation of a compressed shell in which new stars form ("positive feedback") when the gas becomes gravitationally unstable (9, 10). While observations reveal that bubbles are common in regions of massive star formation (11, 12), the relative importance of the effects of positive and negative feedback from high-mass stars on future star formation is unknown.

RCW 120 is a nearby (~1.7 kpc) HII region with a physical diameter of ~4.5 pc (13). The region is ionized by a single O8V star, CD ~38°11636 (LSS 3959) (14), and is known for its near-perfect circular symmetry at mid-infrared (IR) wavelengths (15, 16). The expansion of the HII region has presumably led to the formation of massive clumps along the boundary that are the sites of recent and ongoing star formation (17–20). RCW 120 is considered to be the prototypical triggered star formation source given the simple context of triggered star formation, RCW 120 has been studied extensively through observations (15, 16, 18, 19, 21–24) and simulations (25–29).

RESULTS AND DISCUSSION

Observations of RCW 120

We have used the upGREAT (German Receiver for Astronomy at Terahertz) instrument on the Stratospheric Observatory for Infrared Astronomy (SOFIA) to survey RCW 120 in the [CII] 1.9-THz fine-structure line of ionized carbon. These observations are part of the SOFIA FEEDBACK legacy program dedicated to study the interaction of massive stars with their environment (30). We have also used the Large APEX sub-Millimetre Array (LAMMA) instrument on the Atacama Pathfinder Experiment (APEX) to observe the J = 3–2 isotopologues of CO (see Materials and Methods).

The strongest [CII] emission toward RCW 120 is found in a limb-brightened ring surrounding the HII region, with lower integrated intensities toward the HII region interior (see Fig. 1). The [CII] emission is morphologically similar to the 8-µm emission, which is a reliable tracer of the photodissociation region (PDR), the interface between the fully ionized HII region, and the surrounding neutral and molecular gas. The 12CO(3-2) and 13CO(3-2) emission around RCW 120 is found in denser clumps and filaments compared to that of [CII]. Although we have not observed the northwestern quadrant of the region in [CII], our CO measurements indicate that the ring is open toward the north and shows evidence for punctures in several locations.

Kinematic analysis of the [CII] data reveals a blue-shifted shell, which is visible as a curved structure in position-velocity (p-v) diagrams (see Fig. 2). The morphology of the emission is roughly isotropic, consistent with that of a half-shell expanding toward us at ~15 km/s. Expansion signatures are absent in 12CO(3-2) and 13CO(3-2) emission. This implies that the C*/C/CO transition lies in the ambient molecular cloud beyond the shell. We also detect faint, but widespread, [CII] emission from the bubble interior at the...
systemic velocity of the large-scale cloud [−7.5 km/s, as determined from the APEX CO(3-2) data and Mopra CO(1-0) data (18)] and also, at some positions, at positive (red-shifted) velocities. The red-shifted emission indicates expansion with a velocity of ~10 km/s away from us with respect to the systemic velocity of the cloud (see the Supplementary Materials). While this signature is blended with that of the systemic [CII] emission in the p-v diagrams, it is seen as a separate component in a number of individual spectra toward the region. The red-shifted shell is less massive and more clumpy than the blue-shifted shell and may reflect localized punctures through the molecular gas found at the backside of RCW 120.

Given the expansion velocity of the [CII] shell, we estimate the dynamical age of the region to be ~0.15 million years (Ma), lower than previous estimates (15, 20), but roughly consistent with radiation-hydrodynamics simulations (31). The morphology of RCW 120 suggests that, with the exception of the background cloud at the systemic velocity, the entire shell is expanding at ~15 km/s.

**Diffuse x-ray emission**

The Chandra x-ray observatory has measured diffuse x-ray emission toward RCW 120, revealing the existence of hot (4 × 10^6 K) plasma created by the stellar wind from CD −38°11636 (32); see Fig. 3. Toward the dense southern shell, the hot plasma is confined to the interior of the bubble, but it has ruptured the shell toward the east and the north. [SII] observations show that the 10^4 K HII region gas is primarily found toward the edges of the region (33). We find a filling factor of ~0.2 for the HII region gas (see the Supplementary Materials), suggesting that the remaining ~80% of the bubble is filled with the hot x-ray plasma.

**Stellar wind feedback and energetics**

The picture that emerges from the wealth of our data reveals that the ~2500 km/s (34) wind from CD −38°11636 is shocked, creating a hot plasma that radiates in x-rays (Figs. 3 and 4). The overpressurized hot gas drives a strong shock wave, sweeping up the surrounding medium into a dense shell (6). This shell is ionized on the inside by extreme ultraviolet (E > 13.6 eV) photons, radiating in Hα and [SII] (15, 33). The remainder of the shell consists of neutral gas in a PDR created by impinging far ultraviolet (6 < E < 13.6 eV) photons (35). The PDR is traced by the 8-μm emission of polycyclic aromatic hydrocarbon molecules and by its dominant cooling line, the [CII] 1.9 THz fine-structure line (36); see Fig. 1.

The total kinetic energy of the expanding shell is 1 × 10^{47} to 13 × 10^{47} erg, which is a considerable fraction of the mechanical luminosity of the stellar wind over the age of the bubble (15 × 10^{47} erg). By comparison, the thermal energies of the ionized gas and the hot x-ray plasma are 5 × 10^{46} and 17 × 10^{46} erg, respectively (see Table 1). The ratio of the kinetic energy of the swept up shell to the thermal energy of the hot plasma is possibly much larger (up to a factor of ~8) than predicted for adiabatic expansion of stellar wind bubbles of 1.2 (6). The thermal energy may be reduced because of the breach in the northeast, where hot plasma appears to be leaking out of the HII region. Hot gas is also flowing out through the northern opening of the shell (Fig. 1), which may have further reduced the
thermal energy of the plasma. The x-ray emission from the plasma in the north is likely obscured by a higher column density of neutral foreground gas. Furthermore, this ratio does not take into account electron conduction of the hot gas into the shell balanced by mass evaporation of shell gas into the hot gas and rapid radiative cooling in the mixing layer. This mass loading dissipates additional thermal energy, while simultaneously decreasing the pressure in the bubble. While the leaking hot gas may have stopped to inject energy into the expanding shell, the breaches in the northeast may have occurred recently enough that this would have only a small effect on the kinetic energy of the shell. We find a thermal pressure of $3 \times 10^4$ K cm$^{-3}$ in the surrounding molecular cloud in which the shell is expanding, and a ram pressure from the stellar wind of $8 \times 10^5$ K cm$^{-3}$, which is similar to the measured thermal pressure of the hot x-ray plasma of $7 \times 10^5$ K cm$^{-3}$.

In a system in which the ionizing star is moving supersonically with respect to the ambient cloud, a bow shock forms ahead of the star. The open shell toward the north of RCW 120 and the offset of the star from the center of the bubble are reminiscent of bow shock models for ultracompact HII regions such as G29.96-0.02 (27, 37–40). In these models, a “stationary” shell structure (in the rest frame of the star) develops rapidly at the standoff distance of the bow shock that channels the flow of the material around it. The hot plasma, confined by the shell, is forced to flow downstream, where it quickly punches through the shell. A detailed model developed specifically for RCW 120 (27) explains the observed morphology well for a $<~4$ km/s motion of the star in the plane of the sky, consistent with its estimated proper motion of 2 to 4 km/s (22).

However, the mass flow around the shell in this model is at variance with the velocity field revealed by our observations. These models suggest that convection of energy and mass across the contact discontinuity between the hot plasma and the photo-ionized inner shell gas leads to rapid cooling and, as the thermal energy added by the wind is quickly lost, the expansion stalls. At that point, the main flow of the neutral gas is along the shell walls. Given the observed rapid expansion, we conclude that these models overestimate the energy and mass transfer across this boundary possibly because energy conduction by electrons is greatly limited by the magnetic field (41). As argued below, however, substantial magnetic fields are unlikely in RCW 120, and this effect possibly does not play a role in this source. In addition, the structure of the boundary in the model is determined by numerical diffusion, rather than by physical processes such as thermal conduction (27). We also see little evidence for Kelvin-Helmholtz instabilities that could mix cold shell gas into the hot plasma. The 24-μm dust arc observed at a distance of 0.25 pc from the star indicates a smooth flow of the ionized gas from the (southern) ionization front into the bubble and then on toward the north (27, 42).
expanding more homogeneously, suggesting that the foreground molecular gas is not strongly blocking the shell. The surrounding large-scale molecular background cloud moves with a velocity of 2 to 4 km/s to the north with respect to the ionizing star. Possible for the triggered star formation observed near the region edges. The shell is punctured toward the east and open toward the north, where the hot plasma is leaking into the surrounding medium. The systemic [CII] emission at a velocity of ~7.5 km/s originates from these regions. The back side expands freely at several locations, giving rise to the red-shifted [CII] shell. Toward the front, the shell is expanding more homogeneously, suggesting that the foreground molecular gas is not strongly blocking the shell.

In addition, the morphology of the IR and x-ray observations reveal the presence of a puncture of the shell on the east side (Fig. 3). The surrounding cloud toward the rear side of the region has partially stopped the expansion of the shell in that direction. However, the [CII] velocity data suggest that the shell has also been punctured toward the rear side. This has allowed some of the x-ray emitting gas to flow out into the surrounding filamentary structure of the background cloud. The fact that these punctures predominantly occur toward the shell in the rear but not the front may be connected to instabilities caused by the interaction of the hot plasma within the bubble with the shell. There is no evidence that either the leakage or the surrounding cloud have stopped the expansion of the shell in any other direction. While traditional uniform background density models provide no explanation for such punctures, smoothed particle hydrodynamics models using an initial fractal density structure are able to reproduce perforations in the shell (26). This model, however, assumed that preexisting clumps are compressed by ionization erosion, for which we do not have evidence here. Further numerical simulations (see the Supplementary Materials) may help in determining the origin of these effects.

**Triggered star formation**

Morphologically, the star-forming CO clumps visible in Fig. 1 are part of the shell and are formed by compression in situ as preexisting clumps would be quickly left behind by the expanding shell inside the ionized gas/plasma bubble. Given the absence of pillars and globules in RCW 120, which are typically found in simulations with high fractal dimensions (43), we believe that the initial molecular cloud was fairly homogeneous, making a substantial number of preexisting clumps unlikely. The densest clumps in the shell have already formed stars (see the Supplementary Materials). As a corollary, star formation must have proceeded very rapidly after shell formation. The shell expands supersonically into the background cloud, shocking the swept up gas at 15 km/s. The shocked gas will cool rapidly and that greatly increases the density. For a thin shell \( N_H < -5 \times 10^{21} \text{ cm}^{-2} \), the [CII] fine-structure line will limit the cooling to about \( T > -100 \text{ K} \) in the PDR side facing the star, corresponding to a sound speed of \( >1 \text{ km/s} \) in the PDR. This implies a compression by a factor \( \left( v_s/c_{PDR} \right) \) of \( <200 \) (where \( v_s \) is the speed of the shell and \( c_{PDR} \) is the sound speed in the PDR). For larger column densities, CO can form in the PDR, cooling the gas down to \( >20 \text{ to 30 K} \). At 30 K, the sound speed is \( -0.5 \text{ km/s} \), and the resulting compression is then a factor of \( 1000 \). With a preshock density of \( 10^5 \text{ cm}^{-3} \) (see the Supplementary Materials), the clump density is estimated to be \( 10^7 \text{ cm}^{-3} \). The fastest collapse time scale is the free-fall time scale, \( t_{ff} = 0.06(10^5 \text{cm}^{-3}/n)^{1/2} \text{ Ma} \). Assuming a lower preshock density of \( 10^2 \text{ cm}^{-3} \), the clump density would be \( 10^5 \text{ cm}^{-3} \), corresponding to a free-fall time of 0.2 Ma. With an estimated lifetime of \( 0.15 \text{ Ma} \) for the bubble, the shell itself has not had the time to collapse, but the densest CO clumps would have had enough time to form stars after being compressed by the expanding shell. Several of the densest clumps have already formed stars, particularly in the more highly compressed shell toward the south of the region.

The absence of an expansion signature in \( ^{12}\text{CO}(3-2) \) and \( ^{13}\text{CO}(3-2) \) emission is at first glance unexpected as simulations qualitatively suggest that gas is “pushed away” during the expansion of the HII region (44). Although this may appear intuitive, models show that the difference between the initial velocity of the cloud and that of formed clumps after being compressed by an expanding shell is small (on the order of one to a few kilometers per second) (44). For the CO structures in the backside of the HII region, the expansion would naturally be much slower than that of the [CII] shell due to the large density variations between the clump and interclump gas, whereas any motion of the dense, star-forming clumps in the southern ring would be perpendicular to the line of sight and therefore not detected spectrally. These results are consistent with the observed \( ^{12}\text{CO}(3-2) \) and \( ^{13}\text{CO}(3-2) \) velocity structure and that of clumps formed by cooling and compression in the expanding shell.

In a future study, we intend to discuss the origin scenario of RCW 120, to investigate the hypothesis that the region was formed by the collision of two molecular clouds (27). In this scenario, the
A broad range of models show that magnetic fields can be frozen in the compressed shell and this would cushion the shock, limiting its compression efficiency. Models show that magnetic fields are, in general, preferentially oriented parallel to the shock, limiting its compression efficiency. However, further gravitational collapse of fragments is likely to take longer due to the strong magnetic support. Further magneto-hydrodynamics studies, including self-gravity, will be required to determine the influence of magnetic fields on the collapse of wind-driven shells.

We note that the Veil nebula in Orion—the shell driven by the stellar wind from θ¹ Ori C—shows no evidence for triggered star formation. This may reflect its limited column density and the absence of CO condensations. Alternatively, these differences may result from the presence of a substantial magnetic field in the Veil of $|B| > 50 \mu G$. Half of all Galactic massive star formation regions create IR bubbles. If rapid expansion is a general characteristic of star-forming regions, our results have major ramifications for the study of galaxy formation in the early universe and their subsequent evolution. Little is known about the formation mechanisms of stars in the early universe. As the environment then was metal-poor, the stars are expected to have been massive and therefore would have produced strong feedback effects. Our observations suggest that rapid triggered star formation around these massive stars may have played an important role, possibly contributing to the large star formation densities observed in high-redshift galaxies. A broader survey of massive star formation regions in [CII] emission, as is currently undertaken in the SOFIA FEEDBACK legacy program (30), is required to understand the role of massive stars in the collection, compression, fragmentation, and collapse of molecular clouds.

MATERIALS AND METHODS

The [CII] line at 1.9 THz was observed with SOFIA on 10 June 2019 on a flight from Christchurch, New Zealand, using upGREAT. The map was split into four tiles (each covering an area of $7.26^\circ \times 7.26^\circ$), of which three were observed. Each tile was mapped four times in total-power array-on-the-fly mode. The first two coverages were done once horizontally (along right ascension) and once vertically (along declination), with the array rotated by 19° on the sky. The second two coverages were shifted by 36° to achieve the best possible coverage for the [OI] line (which was observed in parallel but is not discussed here). The final map is centered on Right Ascension (RA), Declination (Dec) ([2000] = 17°12′03.65″, −38°30′28.43″). A fast Fourier transform spectrometer with 4 GHz instantaneous bandwidth was used as the backend. The velocity resolution of the final data is 0.2 km/s. The intensity is given in units of main beam brightness ($T_{MB}$), assuming a forward efficiency, $\eta = 0.97$, and an average main beam efficiency of 0.65. The half-power beam width at 1.9 THz is 14.1″ and the final data have a pixel size of 5″. The root mean square (rms) main beam brightness is 1.8 K for 5″ pixels and 0.2 km/s velocity channels. The scientific objectives and technical details of the FEEDBACK program can be found at https://feedback.astro.umd.edu/ (30).

To improve the quality of the spectra, we identify systematic variations of the baseline originating in instabilities in the telescope system (namely from the backend, receiver, and telescope optics).
The beam width at 345.8 GHz is 18.2″ and the final data cubes are direction, resulting in a uniformly sampled map with high fidelity. Of 9.1″ (half the beam size) and oversampling to 6″ in scanning.

The backends are advanced fast Fourier transform spectrometers of the upGREAT low-frequency array (LFA) receiver and for each SOFIA flight where RCW 120 was observed. The PCA produces a set of components that describe the variance in the spectral structure over the course of the observations from which the baseline artifacts originate. We then reconstruct each ON-OFF spectrum containing information on the astronomical source in terms of these components via a linear combination. Here, a component is more strongly weighted the better the component describes the structure of the spectrum. Because the components are derived from a different set of observations than the ON-OFF spectra, only features characteristic to both sets of spectra will be included in this reconstruction. We lastly subtract each component from the ON-OFF spectrum. This process allows the removal of complex artificial features from a spectrum, which cannot be removed with a standard polynomial baseline fit.

RCW 120 was also mapped on 21 September 2019 in the $^{13}$CO(3-2) and $^{12}$CO(3-2) transitions at 330.6 and 345.8 GHz using the LAsMA array on the APEX telescope (54). LAsMA is a 7 × 7 single polarization heterodyne array that allows simultaneous observations of the two isotopomers in the upper ($^{13}$CO) and lower ($^{12}$CO) sideband of the receiver, respectively. The array is arranged in a hexagonal configuration around a central pixel with a spacing of about 15 × 15′′ split into four tiles. Each tile was scanned in both right ascension and declination with a spacing of 9.1″ (half the beam size) and oversampling to 6″ in scanning direction, resulting in a uniformly sampled map with high fidelity. The beam width at 345.8 GHz is 18.2″ and the final data cubes are gridded to a pixel size of 9.1″. The rms main beam temperature noise of the data is 0.5 K when resampled to 0.1 km/s in velocity.

**Acknowledgments:** This study was based on observations made with the NASA/DLR Stratospheric Observatory for Infrared Astronomy (SOFIA). SOFIA is jointly operated by the Universities Space Research Association Inc. (USRA), under NASA contract NAS2-97001, and the Deutsches SOFIA Institut (DSI), under DLR contract 50 OK 0901 to the University of Stuttgart. upGREAT is a development by the MPI für Radioastronomie and the KOSMA/Universität zu Köln, in cooperation with the DLR Institut für Optische Sensorsysteme. APEX is a collaboration between the Max-Planck-Institut für Radioastronomie, Onsala Space Observatory (OSO), and the European Southern Observatory (ESO). We thank M. Sánchez-Cresu for helpful review of the [CII] observations of RCW 120. **Funding:** We acknowledge funding by the Bundesministerium für Wirtschaft und Energie through the grant FEEDBACK (50OR1916). N.S. and R.S. acknowledge support from the ANR and DFG grant “GENESIS” (ANR-16-CE02-0035-01/DFG1591/2-1). The GREAT team members of the I. Physik. Institut, Universität of Cologne, and Max-Planck Institut für Radioastronomie, Bonn, acknowledge funding from the DFG, project number SFB 956, projects A4, D2, and D3. L.D.A. acknowledges support from NSF grant AST1516021. A.Z. thanks the support from the Institut Universitaire de France. Financial support for the SOFIA Legacy Program, FEEDBACK, at the University of Maryland was provided by NASA through award SOF070077 issued by USRA. **Author contributions:** A.G.G.M.T. and N.S. conceived the FEEDBACK legacy survey, which motivated this study. M.L. and A.G.G.M.T. wrote the manuscript with input from all other authors. M.L. analyzed the data and generated the figures under L.D.A.’s guidance. R.S., C.B., J.S., K.J., M.J., and B.K. generated and processed the SOFIA [CII] observations. R.G. generated and processed the APEX CO observations. S.K., N.S., A.G.G.M.T., L.D.A., R.S., M.R., C.G., D.L., M.T., A.Z., and D.R. assisted on the analysis and interpretation of the [CII] and CO data. L.K.T. and P.S.B. analyzed and interpreted the Chandra x-ray data. All authors discussed the results. **Competing interests:** The authors declare that they have no competing interests. **Data materials and availability:** The [CII] data used in this study are publicly available in the SOFIA Science Archive at IRSA (https://irsa.ipac.caltech.edu/). All data needed to evaluate the conclusions in the paper are present in the paper and/or the Supplementary Materials.
