A universal holographic prediction for quantum-critical dynamics

Sergei Khlebnikov

Department of Physics and Astronomy, Purdue University, West Lafayette, IN 47907, USA

We consider decay of an initial density or current perturbation at finite temperature \( T \) near a quantum critical point with emergent Lorentz invariance. We argue that decay of perturbations with wavenumbers \( k \gg T \) (in natural units) is a good testing ground for holography—existence of a dual gravitational description—in experimentally accessible systems. The reason is that, computed holographically, the decay rate at large \( k \) depends only on the leading correction to the metric near the boundary, and that is quite universal. In the limit of zero detuning (when the temperature is the only dimensionful parameter), the result is a scaling law for the decay rate, with the exponent that depends only on the dimensionality. We show that this follows from an analytical argument and is borne out by a numerical study of quasinormal modes.

Recently, much attention has been attracted to real-time dynamics in conformal field theories (CFTs), especially those capable of describing interacting quantum critical points of interest in condensed matter physics [1]. When the interactions are strong, the quasiparticle picture is not inapplicable for interpretation of the zero-temperature (\( T = 0 \)) spectrum, and one needs new ideas on how to think about relaxation and transport in the \( T \neq 0 \) fluid. One such idea, originally developed in the context of string theory [2–4] (for a review, see Ref. [5]), is holography, according to which certain types of strongly-interacting CFTs have an equivalent (dual) description in terms of string theory or gravity in an extra-dimensional space. This has been applied to a study of quantum critical transport in a CFT with a known gravity dual in Ref. [6]. For a review of holography from the condensed matter perspective, see Ref. [7].

Most of the current dual gravity proposals are for gauge theories; in addition, for gravity to be semiclassical, the number \( N \) of colors in the gauge theory must be large [2]. One may ask if holography-based methods can at all be extended to a broader class of theories. An existing approach is to think of holography as a method of analytical continuation of results obtained in the Euclidean (imaginary time) signature to real time [8]. In that approach, one fits the Euclidean data, assumed available through other means, by a gravity dual with a few free parameters and then uses the result for making predictions for quantities measurable in real time. For example, it has been found [8] that a good fit to the Euclidean conductivity at the O(2) fixed point in (2+1) dimensions can be obtained with only one additional field, corresponding to a relevant operator in the CFT. A holographic model in which this field becomes dynamical has been constructed in Ref. [9].

A different approach, which we adopt here, is to forgo reconstruction of the extra-dimensional (“bulk”) geometry and focus instead on “seeing” a region near the boundary. Consider, as we do throughout this paper, a CFT that has a (possibly emergent) Lorentz invariance. Then, according to the holographic correspondence [2–4], the near-boundary geometry is asymptotically anti-de Sitter (AdS). At temperature \( T \neq 0 \), there is a small metric correction, due to a black hole residing in the AdS bulk. The question we ask is whether it is possible to detect the metric correction by making measurements (ultimately, in the laboratory) that are defined on the CFT side. The answer is non-obvious because, as just discussed, there are additional bulk fields that may have nontrivial profiles. It is true, for instance, that a scalar corresponding to a relevant operator (one with a scaling dimension \( \Delta < d \) in a \( d \)-dimensional CFT) vanishes at the boundary, but so does the metric correction. It is not obvious if one can detect the latter without worrying about the former.

The measurements we have in mind are of the rate of relaxation of an initial perturbation. We consider CFTs (such as the already mentioned O(2) fixed point) that have a conserved current density, \( J^\mu \), and study relaxation of an initial nonzero average \( \langle J^\mu \rangle \) to the equilibrium (zero) value. The index \( \mu \) runs over all \( d \) values, \( \mu = 0, \ldots, d - 1 \); in particular, the temporal component \( J^t \equiv J^0 \) is the corresponding change density. In linear response theory, the process is governed by singularities of the retarded Green function of \( J^\mu \) in the complex frequency plane. The setup then is mostly the same as in Refs. [6, 8, 10], except that we focus on a particular kinematic region: we consider perturbations whose wavenumbers \( k \) are large, \( vk \gg T \), where \( v \) is the effective “speed of light” characterizing a Lorentz-invariant CFT. The corresponding complex frequency is near the light cone, \( \omega \approx vk \). In what follows, we use units in which \( v = 1 \).

For most of the paper, we consider the case when \( T \neq 0 \) is the only deformation from exact criticality, meaning that the coupling constants are all at their critical values—the so-called zero detuning limit. More precisely, we consider cases in which the metric near the boundary can be brought to the form

\[
ds^2 = \frac{R^2}{\lambda_4 u^2} \left[ -f(u) dt^2 + dx^2 \right] + \frac{R^2 f(u)}{u^2} du^2, \tag{1}
\]

where \( u \) is the radial coordinate such that the boundary is at \( u = 0 \), \( R \) is the AdS curvature radius, and \( f(u) \) has
the following small-$u$ asymptotics:

$$f(u) = 1 - u^d + \ldots$$  \hspace{1cm} (2)

Of $\ell(u)$, we require only that $\ell(u) \to 1$ at $u \to 0$. The parameter $\lambda_T$ is a result of rescaling $u$ to make the $u^d$ correction in (2) have the unit coefficient. For a black hole with a planar horizon (a black brane) in otherwise empty AdS, $f(u) = 1/\ell(u) = 1 - u^d$ for all $u < 1$. We refer to this space as (planar) AdS-Schwarzschild (AdSS). In that case, $\lambda_T$ is inversely proportional to the Hawking temperature $T_H$ of the black hole, so even in the more general case (2) we refer to it as the thermal wavelength.

The key is that, although we allow additional fields to deform the metric in the bulk, in Eq. (2) we assume that near the boundary the metric retains the AdSS form, up to and including the $u^d$ correction for $f(u)$. The length $\lambda_T$ does not have to be related to $T_H$ in exactly the same way as for AdSS, but zero detuning implies that it remains inversely proportional to it.

To see why Eq. (2) is plausible, consider for instance the bulk stress tensor of a scalar corresponding to an operator of dimension $\Delta$. By the standard AdS/CFT dictionary [3, 4], the asymptotics of the scalar near the boundary for zero detuning is $\phi(u) \sim u^\Delta$, so the leading term in the stress tensor there is

$$\Theta_{tt} = (\Delta^2 + M^2)A_u u^{2\Delta - 2},$$  \hspace{1cm} (3)

$$\Theta_{uu} = (\Delta^2 - M^2)A_u u^{2\Delta - 2},$$  \hspace{1cm} (4)

where $M$ is the mass of the scalar, in units of $1/R$, and $A > 0$ is a constant. We can use (3) and (4) to find corrections to the functions $f$ and $\ell$ in (1). Because of the relation $\Delta(\Delta - d) = M^2$ [3, 4], the expression (3) for $\Theta_{tt}$ vanishes at $\Delta = d/2$. Otherwise, solution of the Einstein equations near the boundary shows that, while $\ell(u)$ receives a correction proportional to $u^{2\Delta}$, the corresponding term in $f(u)$ cancels out. For $\Delta = d/2$, the stress tensor (3)–(4) is formally “resonant” with the $u^d$ term in the metric functions, so one might expect a logarithmic correction. But, because in this case $\Theta_{tt} = 0$, there is in fact none. Thus, the form (2) is quite generic.

In what follows, we argue that, as a consequence of (2), the relaxation rate of $\langle J^\mu \rangle$ at $k \gg T$, in both longitudinal and transverse channels, is governed in most times by a universal scaling law that depends only on the dimensionality.\(^1\) For example, for a Lorentz-invariant CFT in $d = 3$ dimensions, the rate in either channel is of the form

$$-\text{Im } \omega \approx CT^{6/5}k^{-1/5},$$  \hspace{1cm} (5)

where $C$ is a numerical constant. The constants, $C = C_{tr}$ or $C_t$, are different for the two channels, and their ratio (although not each constant by itself) is universal.

We first present an analytical argument in favor of Eq. (5) and then confirm the result by a numerical calculation. Numerically, we find that the corresponding real part of $\omega$ lies above $k$. At a weakly-coupled critical point, scattering of quasiparticles off a density perturbation with $\omega > k$ does not cause Landau damping (as the speed of a quasiparticle is always smaller than the phase velocity $\omega/k$). This suggests that Eq. (5) is specific to strongly-coupled CFTs, in particular, those that develop a holographic extra dimension. A measurement of the relaxation rate at large $k$ then provides a test (a necessary condition) of whether a given critical point belongs to that type. Towards the end of the paper, we discuss prospects for a such a measurement.

The thermodynamic variable conjugate to $J^\mu$ is a vector field $A_\mu$. By the standard dictionary [3, 4], in holography it becomes the boundary value of a Maxwell gauge field, $A_\mu$, propagating in the $(d + 1)$-dimensional bulk. The Maxwell equation, in the presence of additional (charge neutral) fields, is

$$\partial_M \left[ h(u)\sqrt{-g(u)}g^{MN}(u)g^{PQ}(u)F_{NQ}(t, x, u) \right] = 0,$$  \hspace{1cm} (6)

where all indices run over $d + 1$ values, $g_{MN}$ is the metric tensor, $F_{NQ} = \partial_N A_Q - \partial_Q A_N$, and $h$ describes the coupling to the additional fields. For example, in the scenario of Ref. [8], there is one additional field, a scalar $\phi(u)$, and $h(u) = 1 + \alpha \phi(u)$. At zero detuning, $\phi$ vanishes at $u \to 0$ as $u^\Delta$ with $\Delta \approx 3/2$. Here, we require only that $h(u) \to 1$ when $u \to 0$.

Because the metric (1) does not depend on $t$ and $x$, we can look for solutions to (6) in the form $e^{-i \omega t + i k \cdot x}$ times a radial dependence. The AdS radius $R$ scales out of the Maxwell equation. In addition, if we measure $\omega$ and $k$ in units of $1/\lambda_T$, so does $\lambda_T$. So, in what follows, $g_{MN}$ will denote the metric tensor corresponding to (1) with $R = \lambda_T = 1$.

Next, we impose the gauge condition $A_u = 0$ and obtain separate equations for the longitudinal and transverse components of $A_\mu$. The derivation is standard (see, for example, Ref. [6]). Transverse solutions have $A_t = 0$ and $\sum_i \partial_i A_i = 0$ ($i = 1, \ldots, d - 1$ labels the spatial directions in the boundary theory). Their radial dependencies, which we call simply $A(u)$, satisfy

$$\partial_u \left[ w_{tr}(u)g^{uu}(u)\partial_u A \right] + w_{tr}(u)g^{ij}(u) \left[ \frac{\omega^2}{f(u)} - k^2 \right] A = 0,$$  \hspace{1cm} (7)

where $w_{tr} \equiv h\sqrt{-g}g^{ii}$, and $g^{ii} = g^{jj} = u^2$. For the longitudinal modes, it is convenient to work with the “electric” field $Z \equiv w_t g^{uu} \partial_u A_t$, where $w_t \equiv -h\sqrt{-g}g^{tt}$. The mode
equation for $Z$ is
\begin{equation}
\partial_u \left[ \frac{1}{w_1(u) g^{\alpha}(u)} \partial_\alpha Z \right] + \frac{1}{w_2(u) g^{uu}(u)} \left[ \frac{\omega^2}{f(u)} - k^2 \right] Z = 0.
\end{equation}

The values of $A_\mu$ at $u = 0$ deform the system away from criticality and at zero detuning must vanish. This produces the following boundary conditions for the transverse $A$ and the longitudinal $Z$ at $u \to 0$:
\begin{align}
A(u = 0) = 0, \\
\lim_{u \to 0} u^{d-3} \partial_u Z(u) = 0.
\end{align}

The latter is a consequence of the Gauss law and the asymptotics $w_t g^{\alpha} \to u^{3-d}$.

Poles of the retarded Green function of $J_\mu$ coincide with the quasinormal modes of the field $A_M$, defined as solutions to the mode equations subject to zero detuning conditions at $u \to 0$ and the infalling boundary condition at the horizon $u \to 0$. How should we think about the infalling condition when we only have access to the near-boundary geometry? A useful analogy is with the escape of a photon from a braneworld into a bulk black hole [16]. As in that case, one can define the escape radius $u_c$ by the condition that at $u > u_c$, the solution, say, to Eq. (7) becomes oscillatory semiclassical. If we think of (7) as the Schrödinger equation for an equivalent particle, the wave that is outgoing at $u > u_c$ describes a particle that propagates away from the boundary. Assuming there are no “bumps” at larger $u$ that would reflect the particle back, we can impose the outgoing boundary condition at $u$ somewhat larger than $u_c$, instead of the horizon. If $u_c \ll 1$, the resulting boundary problem will be entirely within the domain of applicability of the small-$u$ limit (2).

We now describe an analytical argument in favor of the scaling law (5) (and similar ones in other dimensionailities). Consider the mode equation (7) for $\omega \approx k$ and large $k$. Assuming $u_c \ll 1$, to be checked a posteriori, take the small $u$ limit. In the potential (second) term, the metric correction gets multiplied by the large $k^2$: we have
\begin{equation}
\frac{\omega^2}{f(u)} - k^2 \approx k^2 u^d + m^2,
\end{equation}
where $m^2 \equiv \omega^2 - k^2$. The enhancement by $k^2$ in (11) is the reason why we will be able to see the $u^d$ correction to the metric even if the rest of the geometry is not known precisely. There is no such enhancement in any other factors, so we can set the remaining metric components to their asymptotic limits and $h(u) \to 1$. A change of variables from $u$ to $\rho = 2k u^{d/2+1}/(d+2)$ and from $A$ to $B$, where $A(\rho) = \rho' B(\rho)$ and $\nu = (d-2)/(d+2)$, brings the resulting (approximate) equation to the form
\begin{equation}
B'' + \frac{1}{\rho} B' - \frac{\nu^2}{\rho^2} B + B = - \frac{m^2}{k^2 \rho^d} B,
\end{equation}
which is the Bessel equation with an additional potential [16]. Purely outgoing waves (resonances) are poles of the corresponding scattering amplitude analytically continued to complex $m^2$ (at real $k$). At fixed $\rho$, $u$ scales with $k$ as $k^{-2/(d+2)}$. Eq. (12) then shows that the locations of the poles can depend only on the combination $m^2 k^{-4/(d+2)}$, so $m^2 \sim k^{4/(d+2)}$ or, equivalently,
\begin{equation}
- \Im \omega \sim k^{(2-d)/(2+d)}.
\end{equation}

For this value of $m^2$, the semiclassical regime for Eq. (12) starts at $\rho \sim 1$, so the condition $u_c \ll 1$ for the escape distance is satisfied. The parallel estimate for the longitudinal channel differs in details but gives the same result (13). In both channels, then, the scaling exponent is the same as that found in Refs. [11–13] for large-$k$ scalar and gravitational modes in the full planar AdS.

We now turn to numerical results. We test universality of the near-boundary limit by using the full planar AdS metric, i.e., Eq. (1) with $f(u) = 1/\ell(u) = 1 - u^d$ for all $u < 1$, and different forms of $h(u)$. If the results do not depend significantly on the choice of $h(u)$, we can infer that we have in fact used only the small-$u$ limit of the theory. For computations, we use the shooting method, starting near the horizon and iterating to obtain a complex $\omega$, for which the solution to (7) or (8) matches the boundary condition (9) or, respectively, (10) at small $u$. A similar method was used for computation of quasinormal frequencies (in a different context) in Ref. [17]. For the full AdS, we can impose the boundary condition directly at the horizon, at $u \to 1$, where (using the transverse channel as an example)
\begin{equation}
A(u) = (1 - u)^s \left[ 1 + c_1 (1 - u) + c_2 (1 - u)^2 + \ldots \right],
\end{equation}
s = - i \omega / d, and the constants $c_1, c_2, \ldots$ are determined from Eq. (7). We then use Eq. (14) to compute $A$ and $\partial_u A$ at $u = 1 - \delta$, offset from the horizon by a small $\delta$. The number of terms in the bracket in (14) should be sufficient to reject the second, $(1 - u)^{-s}$, solution (assuming $2s$ is not an integer). It depends on how large the real part of $s$ is [17]. For example, for $\Re s > -1/2$, keeping only the linear term is sufficient; for $-1 < \Re s \leq -1/2$, one needs also the quadratic term, etc.

To orient ourselves in the complex $\omega$ plane, we first look at the locus of quasinormal frequencies (poles of the corresponding response functions) for small to moderate values of $k$. Fig. 1 shows the frequencies closest to the real axis for $d = 3$ and $h(u) \equiv 1$ (i.e., no coupling to additional fields). At moderate $k$, there are pairs of these located symmetrically about the imaginary axis. At smaller $k$, they collide on the imaginary axis and remain there as $k$ decreases further [10]. In the longitudinal channel, the upper one then proceeds towards the origin, where it becomes the diffusive pole familiar from Refs. [6, 15, 16].

For $d = 3$ and $h \equiv 1$, the Maxwell field in planar AdSS enjoys electric-magnetic duality, as a consequence
We see that the difference is small, reflecting the universality of the near-boundary limit.

In the present work, our main interest is the behavior of the poles for large $k$, when they move beyond the right edge of Fig. 1. In Fig. 2, we show the corresponding values of $\text{Im} \omega$, together with $k^{-1/5}$ fits suggested by Eq. (13). We see that the fits work well. So does the $k^{4/5}$ fit for $|n|^2$ (not shown). In the same figure, we compare results for $h(u) \equiv 1$ and $h(u) = 1 + cu^\Delta$ with $\Delta = 1.5$ and $\alpha = 0.6$, the latter being the value obtained in Ref. [8] by fitting the Euclidean data for the $O(2)$ fixed point. We see that the difference is small, reflecting the universality of the near-boundary limit.

At zero detuning, we can restore the power of $T$ in Eq. (5) on dimensional grounds. Because we do not insist on a particular numerical factor in the relation between $T$ and the thermal wavelength $\lambda_T$ that appears in the near-boundary metric, the constant $C$ in (5) is not universal. The ratio between the constants for the longitudinal and transverse channels, however, is. From the data for $h \equiv 1$ (which we expect to reflect the large $k$ behavior better than those for a general $h$), we find

$$C_l/C_{tr} = 0.30.$$  \hspace{1cm} (15)\hfill

These results are for $d = 3$. For $d = 4$, Eq. (13) predicts $-\text{Im} \omega \sim k^{-1/3}$, which is also borne out numerically.

A candidate system where one may be able to experimentally test the scaling (5) is a gas of repulsive bosons in a two-dimensional optical lattice. The Bose-Hubbard model, commonly used for theoretical description of such a gas, is expected to undergo a quantum phase transition from a superfluid to a Mott insulator, with a critical point ("tip of the lobe") in the $d = 3$ $O(2)$ universality class [18]. Obtaining large homogeneous critical regions in experiment is a challenge. Consider in this context a particular detuning effect—deviation $\delta \mu$ of the chemical potential from the critical value. In holography, this is represented by a nonzero temporal component, $A_t(u = 0)$, of the Maxwell field at the boundary or, in terms of the bulk electric field $Z$, to a nonzero second (subleading) term in the small-$u$ asymptotics $Z(u) = a_1 + a_2 u + \ldots$. Since neither term in the asymptotics affects the correction term in Eq. (2), the scaling law (5) still applies, except that $C$ is now a function of $\delta \mu / T$. The ratio $C_l/C_{tr}$ remains at the universal value (15). Thus, spatial variations of the trap potential in experiment may need to be kept small, but perhaps not prohibitively so.

The author thanks Chen-Lung Hung and Martin Kruczenski for discussions. This work was supported in part by the U.S. Department of Energy (grant DE-SC0019202) and by the W. M. Keck Foundation.
