A critical dimension in the black-string phase transition

Abstract: In spacetimes with compact dimensions there exist several black object solutions including the black-hole and the black-string. These solutions may become unstable depending on their relative size and the relevant length scale set by the compact dimensions. The transition between these solutions raises puzzles and addresses fundamental questions such as topology change, uniquenesses and cosmic censorship. Here, we consider black strings wrapped over the compact circle of a $d$-dimensional cylindrical spacetime. We construct static perturbative non-uniform string solutions around the instability point of a uniform string. First we compute the instability mass for a large range of dimensions, $d$, and find that it follows essentially an exponential law $\gamma^d$, where $\gamma$ is a constant. Then we determine that there is a critical dimension, $d_*=13$, such that for $d \leq d_*$ the phase transition between the uniform and the non-uniform strings is of first order, while for $d > d_*$, it is, surprisingly, of higher order.
In 4d the static uncharged black hole (BH) solutions with a given mass are stable and unique. However, the fundamental theory of nature, which as now believed by many, is the string/M-theory contains more than four dimensions. In this situation the phase space of massive solutions of General Relativity is much more rich and varied. Several phases of solutions exist and transitions between them may occur. For concreteness, we consider the background with a single compact dimension, i.e. with the topology of a cylinder, $\mathbb{R}^{d-2,1} \times S^1$. The coordinate along the compact direction is denoted by $z$ and its asymptotic length is $L$. The problem is characterized by a single dimensionless parameter

$$\mu := G_d M / L^{d-3},$$

where $G_d$ is the $d$-dimensional gravitational constant and $M$ is the mass.

Gregory and Laflamme (GL) [1, 2] discovered that the uniform black string (i.e. a $d - 1$ Schwarzschild solution times a circle, which is the large mass solution) develops a dynamical instability if the compactification radius is “too large”. Their interpretation was that the string decays to a single localized BH. In this case the horizon pinches off and the central singularity becomes “naked”. By now there is a rapidly growing amount of the literature on the subject [3-21]. In particular the scenario of GL was questioned by Horowitz and Maeda (HM) [3] who, on grounds of the classical “no tear” property of the horizons, argued that horizon pinching is impossible and hence a decaying string settles to another stable phase – a non-uniform black string (NUBS). However, a (partial) evidence against that has come from Gubser [4] who in 5d studied perturbative NUBSs emerging from the GL point. He showed that such solutions are too massive and have too low an entropy to serve as an end-state of a decaying critical string. Namely, the transition to this NUBS is of first order and it is again unclear what state is accessed by the classically decaying GL string. Wiseman [7] reached the same conclusion by constructing the NUBS solutions numerically in 6d in a fully non-linear regime. However, in this paper we discover that the transition to NUBS can be smooth depending on spacetime dimension.

Generalizing Gubser’s 5d procedure [4], which is a version of the “marginal stability” method, we construct numerically $d$-dimensional static perturbative NUBS solutions around the GL point. First, we note that the GL instability mass exhibits to a good accuracy an exponential scaling with $d$. Moreover, we find that there is a critical dimension, $d_* = 13$, below which the uniform-nonuniform strings transition is of first order. I.e. it is qualitatively similar to what Gubser has found in 5d. However, above $d_*$ the NUBS solutions emerging from the instability point have a lower mass and a larger entropy than those of the critical string. Namely, the transition between the phases can be continuous.

Hence the NUBS state is accessible by an unstable uniform string. In this case, the horizon would not pinch off at the GL point. Our result suggests, however, that the horizon fragmentation during the classical decay can be avoided only for $d > d_*$. This is a rather curious development since the original HM argument was dimension independent. It should

\[\text{In 5d, [12, 13] could be regarded as additional circumstantial evidences contra the HM claim.}\]

\[\text{This is consistent with the prediction of a critical dimension $\hat{d} = 10$ at the “merger point” of this system, where the string and the BH branches merge [6].}\]
be noted, however, that the central issue of whether any unstable string must decay to a
string remains unresolved even for \( d > d_* \).

The most general ansatz for static black string solutions is
\[
\begin{align*}
\text{d}s^2 &= -e^{2A}f \, \text{d}t^2 + e^{2B} \left( f^{-1} \, \text{d}r^2 + \text{d}z^2 \right) + e^{2C}r^2 \, \text{d}\Omega_{d-3}^2, \\
f &= 1 - 1/r^{d-4},
\end{align*}
\]
where \( A, B \) and \( C \) depend on \( r, z \) only. When these functions vanish the metric becomes
that of a static uniform black string with the horizon located at \( r_h = 1 \).

Gubser [4] has considered static NUBS solutions that differ only perturbatively from a
uniform black string. Since the method was described in detail in the original paper [4] and
then in [7] we mention only the most important points. Gubser developed a perturbation
theory considering the expansion of the metric functions in powers of \( \hat{\lambda} \). This \( \hat{\lambda} \) parametrizes
the NUBS branch that joins the GL point in the limit \( \hat{\lambda} \rightarrow 0 \). The expansion has the form
\[
\begin{align*}
X &= \sum_{n=0}^{\infty} \hat{\lambda}^n X_n(r) \cos(nKz), \\
X_n(r) &= \sum_{p=0}^{\infty} \hat{\lambda}^{2p} X_{n,p}(r), \quad K = \sum_{q=0}^{\infty} \hat{\lambda}^{2q} k_q,
\end{align*}
\]
for \( X = A, B, C \) with \( X_{0,0} = 0 \); and \( K = 2\pi/L \).

Upon substituting (3) into the Einstein equations, \( \text{R}_{\mu\nu} = 0 \), a finite set of ODEs is
generated at each order of the expansion \(^4\). Gubser’s method is very accurate up to the
third order in \( \hat{\lambda} \). Following the original procedure we restrict our computations up to
\( O(\hat{\lambda}^3) \). Nevertheless, interesting results are already obtained here. Actually, the third
order is precisely what one needs to determine the smoothness of a phase transition.

As discussed in [4] the perturbation theory contains a “scheme” dependence that seems
to correspond to different parameterizations of the non-uniform branch. Originally, fixing of
the “scheme” was achieved by fixing the constants \( c_{n,p} := C_{n,p}(r_h) \). Still, other “schemes”
can be used. For example in [7] the asymptotic length of the compact circle was held fixed,
\( K = \text{const} \), but the constants \( c_{n,p} \) were allowed to vary. In fact different “schemes” all
produce the same scheme-independent results, like e.g. the dimensionless mass \((1)\). Here
we choose to work in the “standard scheme”, as it is referred in [4], by fixing
\( c_{1,0} = 1 \).

Once the metric functions are known, various thermodynamical variables can be computed.
Asymptotically the spacetime (2) is characterized by two charges\(^{[16, 19]} \) – the mass and the tension of the black string. By making a Kaluza-Klein reduction in the \( z \) direction,
\( X_{n,p} \) in (3) are observed to be massive modes for \( n > 0 \) and they are massless otherwise.

\(^3\)Gubser used the “non-uniformity” parameter, \( \lambda := 1/2(R_{\text{max}}/R_{\text{min}} - 1) \) where \( R_{\text{max}} \) and \( R_{\text{min}} \) refer
to the \( z \)-dependent Schwarzschild radius of the horizon. Hence \( \hat{\lambda} \) coincides with this \( \lambda \) only at the leading
order. It was shown subsequently in [16, 19] that a good order parameter that allows to put black strings
and holes on the same phase diagram is not \( \lambda \), which is undefined for the latter, but the scalar charge of
the dilatonic field. However, for our current purposes \( \hat{\lambda} \) may be left unspecified.

\(^4\)See e.g. [17] for derivation of the Einstein equations in a very similar case.
Only the latter contribute to the asymptotic charges since the former decay exponentially. Up to $O(\hat{\lambda}^3)$ the relevant massless modes are $X_{0,1}$. Asymptotically, they fall off as inverse powers of $r$. We denote the coefficients of the leading terms by $X_\infty$. It is convenient to define the variation of the charges of a non-uniform string with respect to a uniform one. According to [16] at the leading order these variations read

$$\delta M/M = -2 [A_\infty + B_\infty/(d-3)] \hat{\lambda}^2,$$
$$\delta T/T = -2 [A_\infty + (d-3)B_\infty] \hat{\lambda}^2. \tag{4}$$

We also compute the variation in the temperature, $\delta T/T = \exp[A - B] - 1$, and in the entropy, $\delta S/S = \exp[B - (d-3)C] - 1$, which are evaluated at $r = 1$.

Finally, defining the variation of $K$, $\delta K/K := (k_1/k_0)\hat{\lambda}^2$, we determine the dimensionless, scheme-independent variables by multiplying the dimensional quantities by suitable powers of $K$. By doing so we obtain for our variables

$$\delta \mu/\mu = \delta M/M + (d-4)\delta K/K := \eta_1 \hat{\lambda}^2 + \ldots,$$
$$\delta \tau/\tau = \delta T/T + (d-4)\delta K/K := \tau_1 \hat{\lambda}^2 + \ldots,$$
$$\delta \theta/\theta = \delta T/T - \delta K/K := \theta_1 \hat{\lambda}^2 + \ldots,$$
$$\delta s/s = \delta S/S + (d-3)\delta K/K := s_1 \hat{\lambda}^2 + \ldots. \tag{5}$$

Incorporating the first law as in [4] we evaluate the entropy difference between the non-uniform and uniform strings with the same mass

$$\frac{S_{\text{non-uniform}}}{S_{\text{uniform}}} = 1 + \sigma_1 \hat{\lambda}^2 + \sigma_2 \hat{\lambda}^4 + \ldots,$$
$$\sigma_1 = \frac{d-4}{d-3}s_1 , \quad \sigma_2 = -\frac{d-3}{2(d-4)} \left( \theta_1 + \frac{1}{d-4}\eta_1 \right) \eta_1. \tag{6}$$

The vanishing of $\sigma_1$ is ensured by the first law at the leading order (where $L = \text{const}$)[4]. We verified that to a good ($\lesssim 1\%$) accuracy, $\sigma_1 \approx 0$ for our solutions. Thus, the entropy difference (6) arises only at $O(\hat{\lambda}^4)$.

At each order of $\hat{\lambda}$ we solved the ODEs numerically[22]. We were able to exactly reproduce the numbers found so far in the literature: for 5d in [4] and for 6d in [7]. An indication of the accuracy of the method is gained by varying the “scheme” [4], by altering $c_{0,1} = 0, \pm 1$. The resulting variation in (6) gives an idea of the numerical uncertainty. For small $d$’s the accuracy of our calculation is high, being about 0.5% in $\eta_1$ and 1% in $\sigma_2$. For larger $d$’s the method is somewhat less accurate, yielding 5% and 6% variations in $\eta_1$ and $\sigma_2$ respectively, for $d = 16$. This has to do with the steep asymptotic fall off of $A$ and $B$ in which the leading terms decay as $r^{-(d-4)}$, while $C$ falls off only as $1/r$ (in 5d the fall off is $\log(r)/r$). Hence, the accuracy in extracting the coefficients $A_\infty, B_\infty$, that contribute to $\eta_1$ and $\sigma_2$, decreases for large $d$.

The critical mass. The calculation in the linear order in $\hat{\lambda}$ yields the mass of the critical string, since the leading order of (3) corresponds to the static GL mode. We performed the

\footnote{We use units in which $G_N := G_d/L = 1.$}
Figure 1: The relative difference between the mass and the fit (7), 0.47$\gamma^d$, as a function of $d$. For $\mu_c$ this difference is zero with the spread of about 0.8% magnitude, giving approximately 2.1% variations in $\mu_c$ itself.

calculations in $d = 5, \ldots, 16, 20, 30$ and 50. For $d \leq 10$ we confirm a very good agreement with the original GL results[1], presented in their FIG. 1. Note, however, that the methods are very different. For the entire range of $d$ we find that the critical mass is remarkably well approximated by

$$\mu_c \propto \gamma^d$$  \hspace{1cm} (7)

with $\gamma \simeq 0.686$ being a constant, and the prefactor is approximately 0.47, for the specific definition of mass (1). In FIG. 1 we plot the relative difference between the logarithm of the critical mass and the fit (7). It is clearly seen that log($\mu_c$) is linear for all $d$. There is still room for a weak $d$-dependence, of order 2.1%, around the dominant scaling (7). We, however, could not extract this residual dependence.

To get an insight into this behavior (7) we compute the mass of a uniform black string whose entropy is equal to that of a single BH with the same mass. First we compare the entropy of the black string with that of a d-dimensional Schwarzschild BH. The corresponding entropies read $S_{\text{BH}}^{(0)} = A_{d-2}/(4G_d)$ and $S_{\text{BSH}} = A_{d-3}L/(4G_d)$ where $A_d := \Omega_d[16\pi M/(d\Omega_d)]^{d/(d-1)}$ and $\Omega_d$ is the surface area of a unit $S^d$ sphere. Equating these, $S_{\text{BH}}^{(0)}(\mu) = S_{\text{BSH}}(\mu)$, we solve for the mass

$$\mu^{(0)} = \frac{1}{16\pi} \frac{\Omega_{d-3}^{d-3} (d-3)(d-3)(d-3)}{\Omega_{d-2}^{d-2} (d-2)(d-2)(d-2)}. $$ \hspace{1cm} (8)

Actually, we can do slightly better by using the analytical formula for the entropy of
Figure 2: The trends in the mass, $\mu_{\text{non-uniform}}/\mu_{\text{uniform}} := 1 + \eta_1 \lambda^2 + \ldots$, and the entropy, $S_{\text{non-uniform}}/S_{\text{uniform}} := 1 + \sigma_2 \lambda^4 + \ldots$, shifts between uniform and non-uniform black strings. The key result is the sign change of $\eta_1$ and $\sigma_2$ above $d_* = 13$.

*small* BHs on cylinders derived recently in [21]

$$S_{\text{BH}}^{(1)}(\mu) = S_{\text{BH}}^{(0)} \left[ 1 + \frac{\zeta(d-3)16\pi\mu}{2(d-3)\Omega_{d-2}} + O(\mu^2) \right].$$

(9)

where $\zeta(x)$ is Riemann’s zeta-function. This formula reflects the leading order corrections to the Schwarzschild metric due to compactification. It implies that for a given mass the entropy of a “caged black hole” (a BH in a compactified spacetime) is larger than the entropy of a Schwarzschild BH. The mass $\mu^{(1)}$ corresponding to equality of the entropies is then obtained by solving the equation $S_{\text{BH}}^{(1)}(\mu) = S_{\text{BStr}}(\mu)$.

We add to FIG. 1 the plots for these masses. In contrast to $\log(\mu_c)$ the logarithms of $\mu^{(0)}$ and $\mu^{(1)}$ have a non-linear dependence on the dimension for small $d$’s. They do, however, become linear (with a different slope) for $d \gg 10$. Here we already see a hint of a critical dimension – looking at the difference between $\mu_c$ and its estimator (either $\mu^{(0)}$ or $\mu^{(1)}$) one notices a change of sign at about $d \sim 12.5$. This suggest that for $d \gtrsim 13$ the BH state is entropically favorable over the string state only for $\mu < \mu_c$.

From a sudden to a smooth phase transition. Performing the computation in higher orders, up to $O(\lambda^3)$, we obtain the variation in the variables $\eta_1$ and entropy $\sigma_2$. The results for $\eta_1$ and $\sigma_2$ are depicted in FIG. 2. One observes that $\eta_1$ is initially positive for $d = 5$, reaches a maximum at $d = 10$, and becomes negative for $d > 13$. Then it continues to decrease and in fact it drops increasingly faster with $d$, as indicated by the growing distances between subsequent points in the graph. The pattern for $\sigma_2$ is similar but with

---

*The perturbation theory is constructed in powers of $\mu \ll 1$. 

---
the opposite sign\textsuperscript{7}.

The key phenomena is the appearance of a critical dimension, $d_*=13$, above which the perturbative non-uniform strings are less massive than the marginal GL string. Moreover, their entropy is larger than the entropy of the uniform string with the same mass. It is important that $\eta_1$ and $\sigma_2$ change signs simultaneously.

As for the other variables, we find that the trend in the entropy shift, $s_1$, is qualitatively similar to the behavior of $\eta_1$ – it is positive for $d \leq d_*$ and it becomes negative above $d_*$. For the variation of the temperature we note that below $d_*$ the NUBS is “cooler” than the uniform one and above $d_*$ it is “hotter”. We find that the tension of the non-uniform strings is lower than that of uniform ones. This is in tune with the expectation that the uniform black string has a maximal tension, and that the tension vanishes for small black holes [16, 23]. In addition, we observe the ratios $\eta_1/\tau_1$ and $\eta_1/s_1$ to be discontinuous near $d_*$. Note also that in FIG. 2 we plot the coefficients of the mass and the entropy shifts. To obtain the physical variations these and others coefficients must be multiplied by suitable powers of $\lambda$.

To summarize. While we have found the dependence of the critical mass on the dimension we do not have at present an explanation for the scaling (7). We believe, it gives us some insight into the nature of the GL instability and it probably is connected with the thermodynamical instability of the system[14]. However, it is the appearance of a critical dimension, $d_*$, that can perhaps be regarded as our main result. It implies that above $d_*$ the critical string can smoothly evolve into the NUBS phase. For $d \leq d_*$ the transition between the two phases is of first order.

The continuous transition above $d_*$ suggests that the NUBS phase can be a natural end state of the GL instability. Indeed, a uniform string loosing its mass by evaporation and encountering the instability at $\mu_c$ can smoothly evolve to the non-uniform state keeping its singularity covered by the horizon. Already from FIG. 1 it could be inferred that above $d \gtrsim 13$ there can be a branch of solutions between the uniform strings and the BHs. We believe that the NUBS state is a reasonable candidate for this “missing link”.

As the mass is further radiated away two scenarios may be proposed: (1) The NUBS branch extends to an arbitrary small mass. A black string evolves along this branch probably increasing its non-uniformity all the way down to zero mass. In this case the cosmic censorship would be held (at least until the final stages of evaporation); (2) A NUBS becomes unstable at a finite mass where the horizon fragments and a localized BH forms. This may lead to a compromise of the cosmic censorship, much like in the $d \leq d_*$ case but for a mass smaller than $\mu_c$. The transition between a NUBS and a BH can be sudden or smooth depending on the relative values of the instability masses for these states. Note that a NUBS branch that extends to zero mass or becomes unstable even earlier on a phase diagram is conceptually the same. The main difference is whether the naked singularity shows up before the end of evaporation or not.

To address these intriguing issues it would be a very interesting future task to construct in a fully non-linear regime, like in (6), the branch of NUBSs that we found here. In fact we also did the computation in $d=20$ finding the same trends. However, the numerical errors were of order 20% so we regard this case as an indicative only.

\textsuperscript{7}In fact we also did the computation in $d=20$ finding the same trends. However, the numerical errors were of order 20% so we regard this case as an indicative only.
particular, it is interesting to determine for how low a mass this branch drops, would the horizon try to pinch off forming a cone-like “waist” \[d > d^*\] and whether the topology tends to change. In addition we expect that a time evolution of the critical string, like in \[12\], should confirm a nice decay for \(d > d^*_c\).

In this work we have considered black strings in a cylindrical spacetime. We believe that the critical dimension phenomena is general and will hold for more general backgrounds with additional compact dimensions even if the specific value \(d^*_c = 13\) would change.

I thank B. Kol and T. Piran for stimulating discussions and valuable remarks on the manuscript and Mu-In Park for pointing out an error in the \(\mu^{(1)}\) calculation.
