ECMO complications in COVID-19: A new insight of a controversial disease

Beatriz Amorim Beltrão, Rafael Cabral Teixeira, Diego Bastos Porto

ABSTRACT

Introduction: Extracorporeal membrane oxygenation (ECMO) is a support therapy that can be used in patients with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection and refractory hypoxemia, despite optimal management. However, ECMO may be responsible for a synergic effect in the proposed mechanism of viral associated hyperinflammation.

Case Report: We report a rare case of hemophagocytic lymphohistiocytosis (HLH) in a 58-year-old obese man, who initially responded well to ECMO support and ICU care. He later progressed to a clinical scenario that met criteria for the diagnosis of HLH. Despite our best efforts, the patient had a fatal outcome. To the best of our knowledge, this is the first report of such association.

Conclusion: This case highlights the importance of the appropriate timing in the diagnosis and treatment of SARS-CoV-2 infection and complications, mainly those that are rare and poorly understood, as HLH in patients with ECMO support. The outcomes may be improved with earlier recognition of these grim scenarios.

INTRODUCTION

SARS-CoV-2 pandemics bought many uncertainties to the healthcare professionals’ community. Current knowledge suggests that the cornerstone of therapy in critically ill patients is based on organ dysfunction support associated with corticosteroids [1]. Among the potentially useful support strategies is extracorporeal membrane oxygenation (ECMO). Recently, however, the Extracorporeal Life Support Organization published data with an astonishing 39% mortality rate and high complication incidence associated with this modality [2]. Also, mortality predictions scores were validated such as ISARIC-4C (International Severe Acute Respiratory and Emerging Infections Consortium Coronavirus Clinical Characterisation Consortium) [3]. Aiming to aid in disease comprehension and add new insights to its perspective of complications, we describe a fatal case of a patient with SARS-CoV-2 infection, on ECMO, complicated by the rare diagnosis of hemophagocytic lymphohistiocytosis (HLH), which might have had a different outcome if the diagnosis had been suspected earlier. We highlight the hypothesis of a synergic association between SARS-CoV-2 infection and ECMO, which may contribute to a higher HLH incidence. We also stressed its contribution to deleterious patients’ outcomes, if not suspected early in the evolution.
CASE REPORT

We report a case of a 58-year-old male, with hypertension and obesity (BMI=31 kg/m²), who was admitted to the hospital with a six-day history of daily fever, headache, and dry cough. He also complained of moderate dyspnea, which began 24 hours prior to seeking medical assistance. At the emergency department, he had a breath rate of 25 and an O₂ saturation of 86% on room air. He was started on 6 L/min oxygen, corticosteroids, and a reverse transcription-polymerase chain reaction (RT-PCR) nasal and oropharynx specimen was collected, together with other laboratory exams and a chest-computed tomography (CT) (Table 1, Figure 1). His ISARIC-4C risk score was 12/21, which predicted a mortality rate of 32.9%, at hospital admission. Due to worsening of symptoms and hypoxemia, a decision to intubate was made and he was transferred to the ICU.

On admission, he was started on protective lung ventilation strategy with 5 mL/kg tidal volume and a target driving pressure of 15 or lower. At this point, he was on 100% FiO₂ and arterial blood gas analysis showed a PaO₂ of 70 mmHg. A decision to initiate prone positioning was then made, together with a consultation with the ECMO team. Due to a persistent PaO₂/FiO₂ under 60 and a PCO₂ >80 mmHg, despite optimal therapy, a decision to intubate was made and he was transferred to the ICU.

Our patient initially responded well to ECMO and ultraprotective ventilation strategies, despite having a high predicted mortality rate. He even began to wean sedation and ECMO. However, since the beginning of follow-up, he showed high ferritin and triglycerides levels, had an enlarged spleen, and, on the course of disease, developed a progressive decrease in hemoglobin and platelets (Table 1). Also, around his eleventh follow-up day, he required a new increase in ECMO support. After excluding other etiologies, such as new onset infection and bleeding, based on the clinical picture and evolution, a hypothesis of hyperinflammation and possible HLH was made. After a consultation with hematology, a decision to infuse Etoposide was made as a last resort to revert the potentially fatal evolution. About 72 hours later, the patient was hemodynamically unstable, had multiple bleeding sites and remained without an evident infection site, despite being continuously hyperthermic. He died shortly afterwards.

DISCUSSION

The development of immune complications wasn’t at all anticipated and constituted an exceptional and complex case. Hemophagocytic lymphohistiocytosis is a potential hypothesis to describe some complications of SARS-CoV-2 infection [4]. Its diagnosis is based on clinical and molecular criteria previously described [5] and reinforced by the H-Score [4] prediction. Genetic and functional testing are not recommended for routine use because such abnormalities are rarely detected [5]. Our patient had an initial H-score predicting a 98–99% chance of a diagnosis and fulfilled criteria based on expert consensus [5]. Although the relation among secondary HLH (sHLH) and cytokine release syndrome has been previously discussed in COVID-19 patients, we add the perspective of the possible higher incidence of sHLH in COVID-19 patients due to the influence of ECMO. Thus, ECMO, which by itself can promote sHLH, due to its underlying pathophysiology implications, as other extracorporeal therapies, might have played a key role in this complication [6]. This may be due to a synergic mechanism with the hyperinflammation secondary to viral infection, emphasizing the importance of a high level of suspicion for an early diagnosis and prompt therapy. This scenario may be suspected in patients with high levels of cytokines, ferritin, triglycerides, and other markers as highlighted previously [4, 5]. The potential therapeutic options focus on controlling the inflammatory cytokine production and includes drugs like etoposide [5]. The infusion should occur early in the disease course in order for it to better optimize treatment. This occurs

| Laboratory tests | Follow-up days | Day 1 | Day 3 | Day 4 | Day 6 | Day 8 | Day 12 | Day 15 | Day 17 | Day 18 |
|------------------|----------------|-------|-------|-------|-------|-------|--------|--------|--------|--------|

by minimizing cellular destruction, even though its pharmacodynamics on ECMO are not well established. In this setting, it might even improve outcomes. This remains to be proven in further studies. In spite of that, we stress that, although each isolated scenario (COVID-19 or ECMO) may contribute to sHLH, the exposition to both conditions, simultaneously, as presented in this case report, creates a sHLH setting more prone to happen. This hypothesis also needs to be validated.

CONCLUSION

The potential synergetic effect between SARS-CoV-2 infection and ECMO may play a role in a higher sHLH incidence. This setting may produce an even more challenging clinical scenario. Its prompt recognition and treatment may improve clinical outcomes.
