Vitamin A deficiency has long been known to induce corneal/conjunctival epithelial disorders and keratoconjunctivitis. Vitamin A is therefore considered to be essential for maintenance of ocular surface health and some clinicians have reported its efficacy when used to treat certain corneal disorders (1–4). Promotion of the healing of injury by vitamin A has also been reported in a rabbit model of corneal epithelial detachment (5). The actions of vitamin A include improving keratosis of the corneal/conjunctival epithelium and increasing the conjunctival goblet cell count. We have previously reported that promotion of mucin production by the healing conjunctival epithelium could be a possible mechanism of action for vitamin A (6).

A role of vitamin A in the synthesis of hyaluronic acid by skin cells is well known. Hyaluronic acid is produced by corneal epithelial cells and keratocytes in the eye. We investigated whether rabbit corneal epithelial cells and keratocytes release hyaluronic acid after exposure to vitamin A compounds. Rabbit corneal epithelial cells and keratocytes were inoculated with RCGM2 medium and incubated at 37°C under 5% CO₂ in air for 24 h. The medium was then replaced with medium containing 0.1, 1, 10, or 100 μM retinoic acid or retinol palmitate (V Apal) and incubated for another 48 h. Hyaluronic acid release from both corneal epithelial cells and keratocytes during culture was increased by retinoic acid at the lower concentration of 0.1 μM and 1 μM determined with a sandwich binding protein assay kit. However, it was significantly decreased at the higher concentrations of 10 μM and 100 μM, and the cell count determined with a Neutral Red assay kit was also decreased at these concentrations. On the other hand, hyaluronic acid release from corneal epithelial cells during culture was increased by V Apal at the lower concentration of 0.1 μM and 1 μM, but there was no significant difference in the cell count for either corneal epithelial cells or keratocytes in the presence of V Apal at any concentration. In conclusion, it is suggested that vitamin A stimulates the release of hyaluronic acid from cultured rabbit corneal epithelial cells and keratocytes.

**Key Words** vitamin A, cornea, wound healing, dry eye, cytotoxicity
Corneal epithelial cell suspension (1 thelial cells were purchased as a frozen normal rabbit formed in accordance with the guidelines for animal experimentation at Juntendo University School of Medicine and with the Association for Research in Vision and Ophthalmology (ARVO) Statement for the use of animals in Ophthamlic and vision research.

Preparation of corneal epithelial cells. Corneal epithelial cells were purchased as a frozen normal rabbit corneal epithelial cell suspension (1×10⁶ cells/mL/vial) for secondary culture (NRCE2; Kurabo Industries) (15, 16). After thawing the frozen suspension, the cells were incubated with RCGM2 medium for 5 d at 37°C under 5% CO₂ in air. Then cells were collected by treatment with trypsin and culture was repeated. Cells from the third passage (suspension) were used for the present experiments.

RCGM2 is a serum-free medium (basal medium) with a culture additive (5 µg/mL insulin, 10 ng/mL EGF, 0.5 µg/mL hydrocortisone, 50 µg/mL gentamicin, 50 ng/mL amphotericin B, and 0.4% bovine pituitary extract).

Preparation of keratocytes. Japanese white rabbits (Japan SLC, Inc., Shizuoka, Japan) weighing approximately 3 kg were sacrificed with an overdose of pentobarbital sodium (Nembutal, Dainippon Pharmaceutical Corporation, Ltd., Osaka, Japan). Then the corneas were harvested and the endothelial layer with the epithelium and Descemet’s membrane was detached by using a spatula. The specimens of corneal parenchyma thus obtained were treated with 0.05% collagenase for 1 h and centrifuged for 5 min at 2,000 rpm to collect keratocytes. Then these cells were cultured in minimal essential medium (MEM, Gibco, Life Technologies, Carlsbad, CA, USA) containing 5% fetal bovine serum (FBS) for five passages (the fifth generation of passage culture) before use in the experiments (17).

Culture methods. Corneal epithelial cells and keratocytes were inoculated into 96-well microplates with RCGM2 medium at 2×10⁴ cells/well and incubated at 37°C under 5% CO₂ in air for 24 h. The microplate was covered with its lid during culture. After the medium was replaced with RCGM2 containing 0.1, 1, 10, or 100 µM retinoic acid or VAPal, the cells were incubated for another 48 h (18), and then the conditioned medium was harvested to measure the content (quantity released) of hyaluronic acid. After incubation, the cell count, cell viability, cytotoxicity, and cell proliferation were also determined.

Measurement of hyaluronic acid. The hyaluronic acid concentration of culture supernatant was determined with a sandwich binding protein assay kit (Chugai hyaluronic acid plate; Chugai Pharmaceutical Corporation, Ltd., Tokyo, Japan) according to the manufacturer’s protocol. The assay was based on the specificity of a hyaluronic acid-binding protein isolated from bovine cartilage for hyaluronic acid (19).

After completion of incubation, 50 µL of culture supernatant was collected from each well of the corneal epithelial cell and keratocyte cultures, and mixed with 500 µL of reaction buffer. Then a 100 µL aliquot of each mixture was dispensed into a 96-well microplate (96 HABP Coated Microwells), and the plate was shaken gently and let stand at room temperature for 1 h. Next, the solution in each well was discarded and 300 µL of washing solution was added to each well. After discarding the washing solution, each well was washed another three times. Subsequently, 100 µL of enzyme solution (HRP-conjugated hyaluronic acid-binding protein (HABP)) was added to each well, the plate was shaken gently and let stand at room temperature for 30 min, and then was washed 4 times with washing solution. After 100 µL of color solution (3,3′,5,5′-tetramethylbenzine) was added to each well, the plate was shaken gently and was let stand in the dark at room temperature for 30 min. Finally, the stop solution (100 µL) was added and mixed well, followed by measurement of the absorbance at 450 nm with a microplate reader. The concentration of hyaluronic acid was determined from a standard curve. Data were then presented in terms of ng/mL of culture medium.

Determination of the cell count. The cell count (viability, cytotoxicity, and proliferation) was determined by using a commercially available Neutral Red (NR) assay kit (NR Reagent set; Kurabo Industries, Ltd.) (20–23). This assay is an easy and repeatable method of counting cells that was developed by Borenfreund and Puerner (20, 21). It uses a water-soluble dye (3-amino-7-di methylamino-2-methyl-phenazine hydrochloride (NR), which crosses the plasma membrane and is incorporated into the lysosomes of living cells. As the incorporation of NR is proportional to the number of viable cells, the viable cell count can be indirectly determined.

In brief, cells were cultured with NR according to the manufacturer’s instructions and the number of viable cells was determined from the uptake of dye.

After culture of corneal epithelial cells and keratocytes was completed, the culture medium was replaced by RCGM2 containing 50 µg/mL of NR per well, and the cells were incubated for another 3 h. After discarding the culture medium with NR from each well, 200 µL of formalin solution containing 1% calcium chloride was added to fix the cells, followed by washing and extraction of NR from viable cells with 200 µL of ethanol containing 1% acetic acid (at room temperature 20 min). Subsequently, the absorbance was measured at 540 nm with a microplate reader. Cell counts were expressed as a percentage of the NR incorporation by cells cultured without treatment (control).

Statistical analysis. The Mann-Whitney U test was performed to compare the solvent control culture with each concentration of vitamin A (0.1, 1, 10, and 100 µM) for both hyaluronic acid release and the cell count. All statistical tests were two-sided and significance was accepted at p<0.05. Data were shown as the mean±standard deviation.
the presence of V Apal at concentrations of 0.1 μM and 1 μM. However, hyaluronic acid release was significantly lower after incubation with 10 μM and 100 μM retinoic acid compared with solvent alone. Values represent means±SD from four individual wells. *p<0.05 (Mann-Whitney’s U test).

Fig. 1B. Hyaluronic acid release after the addition of retinoic acid or the solvent alone to corneal epithelial cells. Hyaluronic acid release was significantly higher after incubation with 0.1 μM and 1 μM V Apal compared with solvent alone. Values represent means±SD from four individual wells. *p<0.05 (Mann-Whitney’s U test).

RESULTS

Hyaluronic acid release

Figure 1A shows hyaluronic acid release after the addition of retinoic acid or the solvent alone to corneal epithelial cells. Hyaluronic acid release was 107.8±25.5 ng/mL after addition of the solvent alone, whereas it was significantly higher with 0.1 μM retinoic acid (321.0±23.8 ng/mL, p<0.05) and 1 μM retinoic acid (198.2±16.7 ng/mL, p<0.05). However, hyaluronic acid release was significantly lower after incubation with 10 μM and 100 μM retinoic acid compared with solvent alone (p<0.05).

Figure 1B shows hyaluronic acid release after addition of V Apal or solvent alone to corneal epithelial cells. In the presence of V Apal at concentrations of 0.1 μM and 1 μM, the hyaluronic acid release was 189.2±48.3 ng/mL (p<0.05) and 226.9±50.6 ng/mL (p<0.05) respectively, with both concentrations being significantly higher compared with solvent alone (107.8±25.5 ng/mL). The highest hyaluronic acid release was obtained with 1 μM V Apal, while no significant difference was observed with V Apal at 10 μM or 100 μM.

After addition of retinoic acid to keratocytes, maximum hyaluronic acid release (5,433.6±206.9 ng/mL) was found in the presence of 0.1 μM retinoic acid (p<0.05), whereas the hyaluronic acid level was 4,104.4±571.8 ng/mL after incubation with solvent alone (Fig. 2A). Release was also significantly increased (4,992.0±251.9 ng/mL, p<0.05) by incubation with 1 μM retinoic acid, but was significantly reduced by incubation with 10 μM and 100 μM retinoic acid compared with solvent alone (both p<0.05).

No statistically significant differences in hyaluronic acid release were observed in the presence of V Apal at any concentration (Fig. 2B).
Although no statistically significant differences in the cell count were observed for cultured corneal epithelial cells or keratocytes after addition of retinoic acid at concentrations up to 10 \( \mu \text{M} \) and 100 \( \mu \text{M} \) retinoic acid compared with solvent alone. Values represent means \( \pm \text{SD} \) from four individual wells. *\( p < 0.05 \) (Mann-Whitney’s \( U \) test). (The results are expressed as percentage of the control cultures.)

In contrast, no significant differences in the cell count were observed for cultured corneal epithelial cells or keratocytes after addition of \( \text{VApal} \) at any concentration. Values represent means \( \pm \text{SD} \) from four individual wells. (The results are expressed as percentage of the control cultures.)

**DISCUSSION**

The ocular surface is similar to the skin in a number of ways. For example, it is constantly exposed to various environmental factors, such as ultraviolet radiation, foreign materials, and trauma. Corneal epithelial cells synthesize hyaluronic acid, as do epidermal keratinocytes (24, 25). Increased hyaluronic acid synthesis and release by epidermal keratinocytes in the presence of vitamin A was first reported in the early 1980s (11). The results of the present study showed that vitamin A promotes hyaluronic acid release by corneal epithelial cells and keratocytes, as has been demonstrated in previous studies of epidermal keratinocytes.

The existence of retinol-binding protein, retinyl ester hydrolase and retinyl palmitate hydrolase in mammals is known (26–28). However, the mechanism of action of vitamin A is yet to be elucidated. The mechanisms of hyaluronic acid production/secretion by retinoic acid and \( \text{VApal} \) in the cornea are also not known. It is known that hyaluronic acid synthetase (HAS) is found not only in the skin but also in the cornea (29). Extensive studies report that in the skin, hyaluronic acid production is promoted by beta-carotene, retinol, retinal and retinoic acid via HAS3 gene expression (30, 31) and by retinyl retinoate via HAS2 gene expression (32, 33). HA production is thought to be promoted through nuclear receptors of metabolized and converted retinoic acid (HAS gene expression) (30–33).

It has been reported that \( \text{VApal} \) is converted into reti-
nol in the skin of mammals and humans (34, 35) and that retinol is metabolized and converted into retinal and retinoic acid (36, 37). Considering that retinol is converted into retinoic acid in cultured corneal epithelial cells and in rabbit corneas, as it also is in skin (38, 39), it is reasonable to assume that in our study, hyaluronic acid production by retinoic acid and VApal in the cornea was promoted through nuclear receptors of retinoic acid and HAS gene expression. A role of epidermal growth factor receptor signaling was also reported (9).

The mechanism of action of vitamin A on corneal epithelial cells is also unknown, but we previously found that improvement of the Rose bengal score preceded improvement of the fluorescein score or repair of keratoconjunctival epithelial damage following administration of VApal during healing of n-heptanol-induced wounds to the ocular surface (6). It therefore seems possible that repair of the mucus layer takes place before repair of keratoconjunctival epithelial damage when vitamin A promotes healing of corneal conjunctival wounds. It could also be suggested that vitamin A acts after repair of the mucus layer because its effect is mediated by enhanced hyaluronic acid release. However, it is still unknown whether vitamin A promotes the secretion and production of mucus by corneal epithelial cells, as it does in the case of conjunctival cells, so further studies are required.

Hyaluronic acid is secreted in very small quantities in corneal epithelial cells and keratocytes (24), but produced in large quantities after corneal injury such as trauma or excimer laser irradiation (40, 41). FitSimmons et al. (41) performed keratectomy from the corneal epithelium to the superficial layer of the parenchyma of rabbit corneas using an excimer laser and found that the hyaluronic acid levels on the 8th and 21st days post-keratectomy were 7.3 μg/g and 14 μg/g, respectively. These levels are approximately similar to the hyaluronic acid level of 4,104.4 μg/g in rabbit corneas, as it also is in skin (34, 35). It is comparable with those tested in the present study, whereas it was seen at concentrations of 0.1 and 1 μM, but hyaluronic acid release and the cell count were reduced by retinoic acid at higher concentrations. This finding might represent a manifestation of the cytotoxicity of vitamin A, which has been reported previously (1, 2, 46). After culture for 48 h with a high concentration of VApal, however, there was low cytotoxicity compared with that of retinoic acid. On the other hand, VApal only increased the release of hyaluronic acid at low concentrations, so higher concentrations may have caused slight cell damage or dysfunction that did not lead to a decrease in the cell count.

VApal promoted hyaluronic acid release by cultured corneal epithelial cells at concentrations between 0.1 and 1 μM. When VApal eye drops (1,000 IU/mL) were administered to animals (6), the concentration in the cornea was calculated to be 1.04 μM, assuming that the ocular transfer rate was 0.1%. This concentration is comparable with those tested in the present study. Cytotoxicity of retinoic acid for rabbit corneal epithelial cells was observed at 10 μM or higher concentrations in the present study, whereas it was seen at concentrations of 6 to 30 μM in a previous study of human epidermal keratinocytes (46). These results are similar. However, this similarity depends on the calculation of concentrations, but these levels may not be almost the same in vivo because of differences between the in vitro and in vivo settings. Moreover, it should be noted that the present results were obtained with cultured rabbit corneal epithelial cells. Whether or not the same mechanisms operate in vivo remains unknown. However, the concentration of VApal, mentioned above (1,000 IU/mL), has been proved to be effective in humans as well as in rabbits, so the pharmacokinetics and in vivo effects may be similar in both species. On the other hand, when the cornea has been damaged, the concentration of vitamin A in the cornea will increase because the barrier function will also be damaged. This is also a subject to pay attention to and study in the future. In this study, the amount of hyaluronic acid released into the conditioned medium was measured, but the amount of hyaluronic acid produced by the cells was not measured. Therefore,
the effect of vitamin A on synthesis of hyaluronic acid released into the conditioned medium was measured, but the amount of hyaluronic acid is a subject to be studied in the future.

Numerous reports have been published concerning the efficacy of vitamin A for corneal epithelial disorders. Further research on vitamin A preparations is needed with respect to their effects on the ocular surface, mechanisms of action, and optimal concentration for safe clinical application to treat ocular surface disorders. Furthermore, the mechanism of the beneficial effects of vitamin A to mucin on corneal and epithelial cells (MUC1, 4 and 16) needs to be clarified (45, 47, 48).

Vitamin A has the disadvantage of being unstable, with degradation caused by oxidation. Moreover, side effects including blepharconjunctivitis have been caused by eye ointments containing retinoic acid. In contrast, the esterase of vitamin A (retinol palmitate) used in this study can be considered to have a high potential for clinical application because of its relatively high stability among vitamin A derivatives and no reported side effects. However, there are still differences between rabbit cell cultures and human eyes in its mechanisms, efficacy and safety, and it is necessary to clarify them before clinical application.
