While the well-established GW approximation corresponds to a resummation of the direct ring diagrams and is particularly well suited for weakly-correlated systems, the T-matrix approximation does sum ladder diagrams up to infinity and is supposedly more appropriate in the presence of strong correlation. Here, we derive and implement, for the first time, the static and dynamic Bethe-Salpeter equations when one considers T-matrix quasiparticle energies as well as a T-matrix-based kernel. The performance of the static scheme and its perturbative dynamical correction are assessed by computing the neutral excited states of molecular systems. Comparison with more conventional schemes as well as other wave function methods are also reported. Our results suggest that the T-matrix-based formalism performs best in few-electron systems where the electron density remains low.

I. INTRODUCTION

The GW approximation1 of many-body perturbation theory2 is becoming a method of choice to target charged excitations (i.e., ionization potentials and electron affinities) in molecular systems.3–7 These so-called quasiparticle energies can be experimentally measured from direct and inverse photoemission spectroscopies. From a more theoretical point of view, GW corresponds to an elegant resummation of all direct ring diagrams from the particle-hole (ph) channel which is particularly justified in the high-density or weakly-correlated regime.8, 9 Within the GW approximation, the self-energy — one of the key quantities of Hedin’s equations1 — reads

$$\Sigma^{GW}(1, 2) = iG(1, 2)W(1, 2)$$  (1)

where $G$ is the one-body Green’s function, $W$ is the dynamically-screened Coulomb potential, and, e.g., $l \equiv (\sigma_l, \mathbf{r}_l, \tau_l)$ is a composite coordinate gathering spin, space, and time variables.

Alternatives to GW do exist. For example, the T-matrix (or Bethe-Goldstone) approximation, first introduced in nuclear physics,10–14 then in condensed matter physics,15–22 and more recently in quantum chemistry,23, 24 sums to infinity the ladder diagrams from the particle-particle (pp) channel and is justified in the low-density or strongly-correlated regime.13–15, 26 While the two-point screened interaction $W$ is the cornerstone of GW, the T-matrix approximation relies on a more complex (four-point) effective interaction — the so-called T matrix — yielding the following self-energy:

$$\Sigma^{GT}(1, 2) = i \int G(4, 3)T(1, 3; 2, 4)d3d4$$  (2)

The natural idea of combining the ph and pp channels is also possible and has been explored, for example, in the Hubbard dimer within many-body perturbation theory (see Ref. 22 and references therein) and the uniform electron gas27 within coupled-cluster theory.26

One of the key features of the T-matrix approximation is its exactness up to the second order thanks to the inclusion of second-order exchange diagrams. This class of diagrams, which are particularly important in few-electron molecular systems28–31 and explain the improvement brought by the second-order screened exchange (SOSEX) correction applied to GW,32–34 are well known to be missing in the GW approximation. Moreover, unlike $W$ in the GW approximation, the T-matrix approximation also contains spin-flip terms; the spin structure of the T-matrix allows one to describe important processes like the emission of spin waves in ferromagnetics.35

In this work, we focus on neutral excitations and we explore how the T-matrix approximation performs within the Bethe-Salpeter equation (BSE) of many-body perturbation theory.36–39

Let us consider closed-shell electronic systems consisting of $N$ electrons and $K$ one-electron basis functions. The number of singly-occupied and virtual (i.e., unoccupied) spinorbitals are $O = N$ and $V = K - O$, respectively. Let us denote as $\psi_{\alpha}(\mathbf{x})$ the $\alpha$th spinorbital and $e_{\alpha}$ its one-electron energy. The composite variable $\mathbf{x} = (\sigma, \mathbf{r})$ gathers spin ($\sigma$) and spatial ($\mathbf{r}$) variables. We assume real quantities throughout this manuscript, $i$, $j$, $k$, and $l$ are occupied orbitals, $a$, $b$, $c$, and $d$ are unoccupied orbitals, $p$, $q$, $r$, and $s$ indicate arbitrary orbitals, $m$ labels single excitations, while $n$ labels double electron attachments or detachments.

II. CHARGED EXCITATIONS

By definition, in the quasiparticle approximation, the one-electron Green’s function is2

$$G(\mathbf{x}_1, \mathbf{x}_2; \omega) = \sum_{\mathbf{x}_1} \frac{\psi_{\alpha}(\mathbf{x}_1)\psi_{\alpha}(\mathbf{x}_2)}{\omega - e_{\alpha} - i\eta} + \sum_{a} \frac{\psi_{\alpha}(\mathbf{x}_1)\psi_{a}(\mathbf{x}_2)}{\omega - e_{a} + i\eta}$$  (3)

where $\eta$ is a positive infinitesimal, and its nature is completely defined by the set of orbitals and corresponding energies that are used to build it. For example, $G^{HF}(\mathbf{x}_1, \mathbf{x}_2; \omega)$ is the Hartree-Fock (HF) Green’s function built from the HF spinorbitals $\psi_{\alpha}^{HF}(\mathbf{x})$ and energies $e_{\alpha}^{HF}$. Contrary to the GW approximation which relies on the (two-point) dynamically-screened Coulomb potential $W$ computed

2) Electronic mail: romaniello@irsamc.ups-tlse.fr
from a ph-random-phase approximation (ph-RPA) problem to
target charged excitations,1,2^ here we consider the GT
approximation where one employs the (four-point) T matrix obtained
from solving the pp-RPA equations.

The non-Hermitian pp-RPA problem reads\(^{40-50}\)
\[
\begin{pmatrix}
A_{\text{pp-RPA}} & B_{\text{pp-RPA}} \\
C_{\text{pp-RPA}} & D_{\text{pp-RPA}}
\end{pmatrix}
\begin{pmatrix}
X_{\text{pp-RPA}}^{N+2} \\
Y_{\text{pp-RPA}}^{N+2}
\end{pmatrix}
= \Omega_{\text{pp-RPA}}^{N+2}
\begin{pmatrix}
X_{\text{pp-RPA}}^{N+2} \\
Y_{\text{pp-RPA}}^{N+2}
\end{pmatrix}
\]  
\tag{4}
where the elements of the various matrices are defined as
\begin{align}
A_{\text{pp-RPA}}^{ab,cd} & = \delta_{ab}\delta_{cd}(\epsilon_a + \epsilon_b) + \langle ab|cd\rangle \\
B_{ab,ij}^{\text{pp-RPA}} & = \langle ab|i j\rangle \\
C_{ij,kl}^{\text{pp-RPA}} & = -\delta_{ik}\delta_{jl}(\epsilon_i + \epsilon_j) + \langle ij|kl\rangle
\end{align}
and
\[
\langle pq|r s\rangle = \langle pq|rr\rangle - \langle pq|sr\rangle
\]  
\tag{6}
are two-electron integrals in the spinoribital basis, i.e.,
\[
\langle pq|r s\rangle = \int \psi_p(x_1)\psi_q(x_2)\frac{1}{|r_1 - r_2|}\psi_r(x_1)\psi_s(x_2)d\mathbf{x}_1d\mathbf{x}_2
\]  
\tag{7}
The pp-RPA problem yields, in the absence of instabilities
(which should not appear in Coulombic systems with repulsive
interactions only\(^{43}\), \(V(V - 1)/2\) positive eigenvalues \(\Omega_{\text{pp-RPA}}^{N+2}\)
and \(O(O - 1)/2\) negative eigenvalues \(\Omega_{\text{pp-RPA}}^{N-2}\), which correspond
differently to double attachments and double detachments.
The pp-RPA correlation energy is given by\(^{42,43}\)
\[
E_{c}^{\text{pp-RPA}} = + \sum_{n} \Omega_{\text{pp-RPA}}^{N+2} - \text{Tr}(A_{\text{pp-RPA}})
\]
\[
= - \sum_{n} \Omega_{\text{pp-RPA}}^{N-2} - \text{Tr}(C_{\text{pp-RPA}})
\]  
\tag{8}

Considering the time structure of the T-matrix approxima-
tion as \(T(1, 3; 2, 4) = -\delta(t_1 - t_3)\delta(t_2 - t_4)\)\(T(x_1, x_2; x_3, x_4; t_1 - t_4)^{2}\) the frequency-dependent T-matrix self-energy can be ob-
tained from the Fourier transform of Eq. (2) as
\[
\Sigma^{GT}(x_1, x_2; \omega) = -i \int dx_3 dx_4 \int \frac{d\omega'}{2\pi} G(x_4, x_3; \omega')
\times T(x_1, x_3; x_2, x_4; \omega + \omega')
\]  
\tag{9}
The correlation part of T matrix can be constructed from
the knowledge of the pp-RPA eigenvalues and eigenvectors. In the
spinoribital basis, it is defined as \(T_{pq,rs}^{c} = T_{pq,rs}^{c} - \langle pq|rs\rangle\) and
it has the following form\(^{49}\)
\[
T_{pq,rs}^{c}(\omega) = \sum_{n} \frac{\langle pq|\chi_{n}^{N+2}\rangle \langle rs|\chi_{n}^{N+2}\rangle}{\omega - \Omega_{n}^{N+2} + i\eta} - \sum_{n} \frac{\langle pq|\chi_{n}^{N-2}\rangle \langle rs|\chi_{n}^{N-2}\rangle}{\omega - \Omega_{n}^{N-2} - i\eta}
\]  
\tag{10}
Combining Eqs. (3) and (10), the correlation part of the T-
matrix self-energy reads\(^{22,24,25}\)
\[
\Sigma_{pq}^{GT}(\omega) = \frac{\sum_{in} \langle pq|\chi_{n}^{N+2}\rangle \langle \delta|\chi_{n}^{N+2}\rangle}{\omega + \epsilon_{i} - \Omega_{n}^{N+2} + i\eta} + \sum_{an} \frac{\langle pol|\chi_{n}^{N-2}\rangle \langle qa|\chi_{n}^{N-2}\rangle}{\omega + \epsilon_{a} - \Omega_{n}^{N-2} - i\eta}
\]  
\tag{12}
While the dynamical GW self-energy corresponds to the down-
folding of the 2h1p and 2p1h configurations on the 1h and 1p
configurations via their coupling with the 1h1p configurations,
respectively.\(^{51}\) Eq. (12) shows that, in the case of the T-matrix
approximation, the same 2h1p and 2p1h configurations are
downfolded on the 1p and 1h configurations via their coupling
with the 2h and 2p configurations, respectively.

Within the (perturbative) one-shot GT scheme (labeled as
\(G_{0}T_{0}\) in the following), the quasiparticle energies are obtained
via linearization of the quasiparticle equation,\(^{52-60}\) i.e.,
\[
\epsilon_{p}^{G_{0}T_{0}} = \epsilon_{p}^{HF} + Z_{p}^{\Sigma^{GT}}(\epsilon_{p}^{HF})
\]  
\tag{13}
where we have assumed a HF starting point and
\[
Z_{p} = \left[1 - \frac{\partial \Sigma_{pp}(\omega)}{\partial \omega}\right]^{-1}_{\omega = \epsilon_{p}^{HF}}
\]  
\tag{14}
is the renormalization factor or weight of the quasiparticle solu-
tion. Other levels of (partial) self-consistency can be consid-
ered like the “eigenvalue” self-consistent GT (evGT)\(^{54-60,64}\)
or the quasiparticle self-consistent GT (qsGT)\(^{63-69}\) schemes.

### III. NeUTRAL EXCITATIONS

Like the one-body Green’s function is the pillar of the GW
and GT approximations, the two-body Green’s function \(G_{2}\) is
the central quantity of the BSE formalism of many-body perturbation
theory\(^{36-39}\) via its link with the two-body correlation
function \(L\) which satisfies the following Dyson equation
\[
L(1, 2; 1’, 2’) = L_{0}(1, 2; 1’, 2’)
+ \int L_{0}(1, 4; 1’, 3)\Xi(3, 5; 4, 6)L(6, 2; 5, 2’)d3d4d5d6
\]  
\tag{15}
where
\[
il_{L_{0}}(1, 4; 1’, 3) = G(1, 3)G(4, 1’)
\]  
\tag{16a}
il_{L_{0}}(1, 2; 1’, 2’) = -G_{2}(1, 2; 1’, 2’) + G(1, 1’)G(2, 2’)
\]  
\tag{16b}
and
\[
\Xi(3, 5; 4, 6) = i\frac{\delta \Sigma(3, 4)}{\delta G(6, 5)}
\]  
\tag{17}
is the so-called BSE kernel that takes into account the variation
of \(\Sigma\) with respect to the variation of \(G\). By taking into account
the interaction of the excited electron and its hole left behind
the infamous excitonic effect), the BSE is able to faithfully
model (neutral) optical excitations as measured by absorption
spectroscopy. The moderate cost of the BSE [which scales
as \(O(K^4)\) in its standard implementation] and its all-round accuracy are the main reasons behind its growing popularity in the molecular electronic structure community.\(^{38,39,64,70–88}\)

In order to target neutral (singly-)excited states, we first consider the static version of the BSE employing the GT quasi-particle energies [see Eq. (13)] as well as the \(T\)-matrix kernel [i.e., \(\Sigma^{GT}\) in Eq. (17)]. In this case, the BSE@\(GT\) linear eigenvalue problem simply reads

\[
\begin{pmatrix}
A_{\text{BSE}} & B_{\text{BSE}} \\
-B_{\text{BSE}} & -A_{\text{BSE}}
\end{pmatrix}
\begin{pmatrix}
X_{\text{BSE}} \\
Y_{\text{BSE}}
\end{pmatrix}
= \Omega_m
\begin{pmatrix}
X_{\text{BSE}} \\
Y_{\text{BSE}}
\end{pmatrix}
\]  

with

\[
A_{\text{BSE}} = \delta_{ij}\delta_{ab}\left(e_a^{GT} - e_b^{GT}\right) + \langle ib|a(j) + T_{i,j,a}(\omega = 0) \tag{19a}
\]

\[
\rho_{\text{BSE}}(\omega) = \langle j||ab(\omega = 0) \tag{19b}
\]

The eigenvalues \(\Omega_m\) of Eq. (18) provide OV singlet (i.e., spin-conserved) and OV triplet (i.e., spin-flip) single excitations. Note that the spin structure of the BSE@\(GT\) equations is analogous to the BSE@\(GW\) version,\(^{89}\) and one can compute separately singlet and triplet excitation energies. Neglecting the coupling between excitations and deexcitations, i.e., \(B_{\text{BSE}} = 0\), is known as the Tamm-Dancoff approximation (TDA).

Due to the frequency-independent nature of the static BSE, it is well known that one cannot access continuous (and higher) excitations.\(^{89–94}\) In order to go beyond the static approximation, it is possible to consider, within the dynamical TDA (dtTDA) that neglects the frequency dependence of the coupling block \(B\), the dynamical version of the BSE (dBSE).\(^{37,91,93}\) In this case, one must solve the (non-linear) dynamical eigenvalue problem

\[
\begin{pmatrix}
A_{\text{dBSE}}(\Omega) & B_{\text{BSE}} \\
-B_{\text{BSE}} & -A_{\text{dBSE}}(\Omega)
\end{pmatrix}
\begin{pmatrix}
X_{\text{BSE}} \\
Y_{\text{BSE}}
\end{pmatrix}
= \Omega \begin{pmatrix}
X_{\text{BSE}} \\
Y_{\text{BSE}}
\end{pmatrix}
\]  

(20)

with

\[
A_{\text{dBSE}}(\omega) = \delta_{ij}\delta_{ab}\left(e_a^{GT} - e_b^{GT}\right) + \langle ib|a(j) + \bar{T}_{i,j,a}(\omega) \tag{21}
\]

where, following Strinati’s seminal work,\(^{37}\) one can derive the following expression for the elements of the dynamical \(T\) matrix

\[
\bar{T}_{i,j,a}(\omega) = \sum_n \frac{\langle ib|X_n^{N+2}\rangle \langle a|X_n^{N+2}\rangle}{\omega - \Omega^{N+2}_m + (e_a^{GT} + e_b^{GT}) + i\eta} + \sum_n \frac{\langle ib|X_n^{N-2}\rangle \langle a|X_n^{N-2}\rangle}{\omega + \Omega^{N-2}_m - (e_a^{GT} + e_b^{GT}) + i\eta}
\]  

where \(\sum \rangle\rangle\) from which, one can check that we recover the static expression (10) in the limit \(\Omega^{N\pm2}_m \to \infty\). Equation (22) highlights the interesting dynamical structure of the \(T\) matrix, where, similarly to the dBSE@\(GW\) scheme,\(^{37,91,93}\) the 2h2p configurations are downfolded on the 1h1p configurations.\(^{85}\) Additional details about the derivation of Eq. (22) are reported in Appendix A.

Because solving a non-linear eigenvalue problem is computationally challenging, here we rely on the perturbative scheme developed in Ref. 93 in order to access dynamically-corrected single excitations for which additional relaxation effects coming from higher excitations are taken into account.\(^{89,91,93,94,96–101}\) Below, we quickly recap this dynamical perturbative scheme.

Based on Rayleigh-Schrödinger perturbation theory, the non-linear eigenproblem (20) can be split as a zeroth-order static reference and a first-order dynamic perturbation, such that

\[
\begin{pmatrix}
A_{\text{dBSE}}(\Omega) & B_{\text{BSE}} \\
-B_{\text{BSE}} & -A_{\text{dBSE}}(\Omega)
\end{pmatrix}
\begin{pmatrix}
X_{\text{BSE}} \\
Y_{\text{BSE}}
\end{pmatrix}
= \begin{pmatrix}
A & 0 \\
0 & -A_{\text{dBSE}}(\Omega)
\end{pmatrix}
\begin{pmatrix}
X_{\text{BSE}} \\
Y_{\text{BSE}}
\end{pmatrix}
\]  

(23)

with

\[
A_{\text{dBSE}}(\omega) = \bar{T}_{i,j,a}(\omega) - \bar{T}_{i,j,a}(\omega = 0) \tag{24}
\]

As usual, one can naturally expand the \(S\)th BSE excitation energy and its corresponding eigenvector as

\[
\Omega_S = \Omega^{S\text{BSE}} + \Omega^{S(1)} + \ldots, \tag{25a}
\]

\[
\begin{pmatrix}
X_S \\
Y_S
\end{pmatrix}
= \begin{pmatrix}
X^{S(1)}_S \\
Y^{S(1)}_S
\end{pmatrix} + \ldots \tag{25b}
\]

Solving the static BSE [see Eq. (18)] yields the (zeroth-order) static \(\Omega_S\) excitation energies and their corresponding eigenvectors \(X^{S\text{BSE}}_S\) and \(Y^{S\text{BSE}}_S\). The first-order correction to the \(S\)th excitation energy is, within the dTDA,

\[
\Omega^{(1)}_S = (X^{S\text{BSE}}_S)^T \cdot \Omega^{(1)} \cdot (Y^{S\text{BSE}}_S) = (X^{S\text{BSE}}_S)^T \cdot X^{S(1)\text{BSE}}_S \tag{26}
\]

This correction can be renormalized by computing, at no extra cost, the renormalization factor which reads

\[
\xi_S = \left[1 - (X^{S\text{BSE}}_S)^T \cdot \frac{\partial \Omega^{(1)}(\Omega_S)}{\partial \Omega_S} \right]_{\Omega_S=\Omega^{S\text{BSE}}}^{-1} \tag{27}
\]

This yields our final expression for the dynamically-corrected BSE excitation energies:

\[
\Omega^{S\text{dyn}} = \Omega^{S\text{stat}} + \Delta \Omega^{S\text{dyn}} = \Omega^{S\text{BSE}} + \xi_S \Omega^{S(1)}_S \tag{28}
\]

Note again that the present perturbative scheme does not allow to access double excitations as only excitations calculated within the static approach can be dynamically corrected.

### IV. COMPUTATIONAL DETAILS

The present formalism has been implemented in the electronic structure package QuAcK\(^{102}\) which is freely available at https://github.com/pfloos/QuAcK. We consider here only systems with closed-shell singlet ground states. Thus, the \(GW\) and \(GT\) calculations are performed by considering a (restricted) HF starting point and standard gaussian basis sets (defined with cartesian functions) are employed. Note that all quasi-particle energies which are obtained via Eq. (13) are corrected in the same way. Finally, the infinitesimal \(\eta\) is set to zero for all calculations. The ev\(GT\) and qg\(GT\) schemes have been also implemented but are not considered here, mainly because,
for the small molecular systems studied here (see below), we have observed very small differences between one-shot and self-consistent quasiparticle energies. Although the dynamical correction is computed in the dTDA throughout, the zeroth-order excitonic Hamiltonian [see Eq. (18)] is always the “full” BSE static Hamiltonian, i.e., without TDA. Reference full configuration interaction (FCI) calculations have been performed with QUANTUM PACKAGE.\textsuperscript{103}

In terms of computational cost, the overall scaling of BSE@GT is equivalent to BSE@GW as they both correspond to seeking the lowest eigenvalues of a matrix of size $(2OV \times 2OV)$. Searching iteratively for the lowest eigenstates can be routinely performed via Davidson’s algorithm with a $O(K^4)$ computational cost.\textsuperscript{104} The cost of the dynamical correction, which is thoroughly discussed in Ref. 93, is more expensive but is again equivalent in both formalisms. The computational cost associated with the computation of the $T$-matrix and the screening $W$ both scale as $O(K^6)$ in their standard implementation as one must obtain all the eigenvalues and eigenvectors of the pp-RPA and ph-RPA problems, respectively.\textsuperscript{105} However, the prefactor of the pp-RPA calculation is significantly larger than its ph-RPA counterpart due to the larger size of the pp-RPA matrices and its non-Hermitian nature.\textsuperscript{42–45,47–49} Moreover, within the $T$-matrix formalism, one must compute both the singlet and triplet contributions of the $T$-matrix, while for singlet states, only the singlet part of $W$ is required. Although similar approaches remain to be developed for the $T$-matrix formalism, contour deformation and density fitting techniques can be efficiently implemented in the case of $GW$ to reduce the scaling to $O(K^3)$.\textsuperscript{106–108}

V. RESULTS AND DISCUSSION

\subsection*{A. Excited states of the hydrogen molecule}

As a first didactical example, we consider the lowest singlet and triplet excited states of the hydrogen molecule $H_2$ and the variation of their respective vertical transition energies upon dissociation. The excitation energies associated with these low-lying excited states are represented in Fig. 1 as a function of the internuclear distance $R_{H-H}$ at the FCI (black), BSE@$G_0W_0$ (blue), and BSE@$G_0T_0$ (red) levels with the cc-pVTZ basis. The variation of the HOMO and LUMO quasiparticle energies as well as HOMO-LUMO gap computed at the $G_0W_0$ and $G_0T_0$ levels is depicted in Fig. 2. This shows that, as already observed in the Hubbard dimer\textsuperscript{22} and in molecular systems,\textsuperscript{24} the $G_0W_0$ and $G_0T_0$ quasiparticle energies are similar near the Fermi level.

Overall, as evidenced by Fig. 1, the performances of BSE@$G_0W_0$ and BSE@$G_0T_0$ are analogous for this system. For the lowest singlet excited state of $B^1 \Sigma^+_u$ symmetry, the $T$-matrix-based formalism is slightly better when $R_{H-H}$ increases but fails ultimately to reproduce the FCI results. For the $E^1 \Sigma^+_g$ state, BSE@$G_0T_0$ is more accurate than BSE@$G_0W_0$ for small bond length and the scenario is reversed after the avoided crossing with the doubly-excited state of $F^1 \Sigma^+_g$ symmetry. Of course, both formalisms cannot “see” the $F^1 \Sigma^+_g$ states as the static BSE formalism is blind to double excitations. Therefore, it cannot model properly the avoided crossing between $E^1 \Sigma^+_g$ and $F^1 \Sigma^+_g$ states. For the $B^1 \Sigma^+_u$ and $C^1 \Pi_u$ states, BSE@$G_0W_0$ and BSE@$G_0T_0$ reproduces fairly well the FCI potential energy curves with a modest preference for the latter.

Similar observations can be made for the triplet states, the $GW$- and $GT$-based formalisms yielding very similar excitation energies, except for the $C^3 \Pi_u$ states for which BSE@$G_0W_0$ has already the edge. Moreover, triplet instabilities seems to affect BSE@$G_0T_0$ slightly earlier than BSE@$G_0W_0$.

In Fig. 3, we show the energy shift provided by the dynamical correction for the lowest singlet and lowest triplet excited states of $H_2$ as a function of $R_{H-H}$. These dynamically-corrected schemes are labeled dBSE@$G_0W_0$ and dBSE@$G_0T_0$. For the singlet state of $B^1 \Sigma^+_u$ symmetry, the dynamical correction improves slightly the excitation energies at small internuclear distances for both schemes, while, for larger bond lengths, an improvement is only visible at the $T$-matrix level. Note that, for this system with few electrons, the dynamical corrections are quite small in magnitude. In the case of the triplet state of $b^3 \Sigma^+_g$ symmetry, the dynamical correction worsens the results compared to FCI, especially in the case of BSE@$G_0W_0$.

\subsection*{B. Excited states of beryllium hydride}

As a second example, we consider the symmetric dissociation of the linear molecule beryllium hydride (BeH$_2$), a system for which one can assume that the screening plays a more important role than in the previous example. The variation of the lowest singlet and triplet excitation energies as a function of the distance $R_{Be-H}$ is shown in Fig. 4, while the quasiparticle energies of the frontier orbitals and the associated (fundamental) gap computed at the $G_0W_0$ and $G_0T_0$ levels is depicted in Fig. 5. All calculations are performed with the cc-pVDZ basis. Again, one notes that the $G_0W_0$ and $G_0T_0$ quasiparticle energies are very similar near the Fermi level. Therefore, one can safely assume that any significant variation of the excitation energies computed within the $GW$- and $GT$-based formalisms originated mainly from their distinct kernel. The excitation energies computed with the dynamical schemes, dBSE@$G_0W_0$ and dBSE@$G_0T_0$, are reported as thin solid lines. Here, one can show that dynamical corrections improves in most cases the agreement between BSE and FCI.

For the four lowest singlet excited states (left panel of Fig. 4), dBSE@$G_0T_0$ is clearly better than dBSE@$G_0W_0$, while the opposite trend is observed for the four lowest triplet states (right panel of Fig. 4). Note that, for large $R_{Be-H}$, the two BSE-based schemes provide only a qualitative description of the excited states with errors of several eV. Nonetheless, the overall ordering of the excited states are globally respected.

\subsection*{C. Excited states of water}

As a third and final example, we compute the excitation energies associated with the two lowest singlet and two lowest triplet excited states of water at equilibrium geometry (see
FIG. 1. Singlet (left) and triplet (right) excitation energies (in eV) of H$_2$ as a function of the internuclear distance $R_{\text{H-H}}$ (in Å) computed at the FCI (black), BSE@$G_0W_0$ (blue), and BSE@$G_0T_0$ (red) levels with the cc-pVTZ basis. Raw data are reported in supplementary material.

Fig. 6). Note that all these excited states are of Rydberg nature and correspond to $n \rightarrow 3s$ and $n \rightarrow 3p$ transitions for the $B_1$ and $A_2$ states, respectively.$^{110}$ In addition to the BSE-based models studied in the present manuscript, we have selected well-known wave function methods,$^{111-114}$ namely CIS, CIS(D), TDHF, and FCI (taken as reference) and computed the excitation energies of these transitions. It is worth mentioning here that the TDHF (or RPAX) equations within the TDA are strictly equivalent to the CIS equation,$^{114}$ and that CIS(D) is a simple perturbative doubles correction to CIS, and can be considered as an excited-state analog of second-order Möller-Plesset perturbation theory.$^{112,113}$

Two key observations can be made: i) BSE@$G_0W_0$ is by far the best performer with a slight overestimation of the order of 0.1 eV (as compared to FCI); ii) BSE@$G_0T_0$ systematically underestimates the excitation energies [similarly to CIS(D)] and outperforms CIS, CIS(D) and TDHF for the singlet states only. These general trends are also observed for other systems and they nicely evidence the crucial role of the screening in $GW$, hinting that a screened version of the $T$-matrix formalism as proposed in Ref. 22 might be a promising way for improvement.

VI. CONCLUSION

We have derived and implemented, for the first time, the static and dynamic Bethe-Salpeter equations when one considers $T$-matrix quasiparticle energies as well as a $T$-matrix-based kernel. The performance of the static scheme and its perturbative dynamical correction have been assessed by computing the neutral excited states of several molecular systems. Our results
FIG. 3. Error with respect to FCI for the lowest singlet (left) and the lowest triplet (right) excitation energies of H$_2$ as a function of the internuclear distance $R_{H-H}$ (in Å) computed within the static schemes (BSE@$G_0W_0$ and BSE@$G_0T_0$) and the dynamically-corrected schemes (dBSE@$G_0W_0$ and dBSE@$G_0T_0$). The cc-pVTZ basis is employed for all calculations. Raw data are reported in supplementary material.

FIG. 4. Singlet (left) and triplet (right) excitation energies (in eV) of BeH$_2$ as a function of the distance $R_{Be-H}$ (in Å) computed at the FCI (black), BSE@$G_0W_0$ (blue), and BSE@$G_0T_0$ (red) levels with the cc-pVDZ basis. The dynamically-corrected BSE excitation energies are represented as thin lines for dBSE@$G_0W_0$ (blue) and dBSE@$G_0T_0$ (red). Raw data are reported in supplementary material.
suggest that, in the context of the computation of molecular excitation energies, the BSE@GT formalism performs best in few-electron systems where the electron density remains low. The overall accuracy of the present scheme still needs to be assessed for larger systems (where the screening is known to be more important). For such purposes, a comprehensive benchmark study would be required and we are planning to do so in the future.

It would be interesting to investigate its performance for the computation of ground-state correlation energies within the adiabatic connection fluctuation dissipation formalism where BSE@GW has been shown to be particularly outstanding\textsuperscript{86,87,115} The combination of GT and GW via the range separation of the Coulomb operator to avoid double counting of the low-order diagrams is also a promising avenue. Work along these lines are currently under progress. Finally, the unrestricted and spin-flip extensions of the present formalism are currently being developed.

Appendix A: BSE with a dynamical T-matrix kernel

In order to derive the dynamical kernel $\tilde{T}_{lba}^{s}$ given in Eq. (22), we follow Ref. 52 (see also Ref. 87) and start from the equation for the BSE amplitude

$$\chi_S(1, 1') = \int d3d4d5d6L_0(1, 4, 1', 3)\Xi(3, 5, 4, 6)\chi_S(6, 5)$$

(A1)

where $L_0$ is given by Eq. (16a) and the $T$-matrix kernel is

$$\Xi(3, 5, 4, 6) = i\frac{\delta\Sigma(3, 4)}{\delta G(6, 5)} \approx -T(3, 5, 4, 6)$$

(A2)

Equation (A1) is derived by assuming that i) the (resonant) pole $\omega_S = E_S - E_0 > 0$ of $L$ is isolated from the other poles (which is usually the case for neutral excitations in finite systems), and ii) the poles of $L_0$ are different from $\omega_S$ (which is also generally the case). The so-called $T$-matrix self-energy $\Sigma$ is given by Eq. (2) with\textsuperscript{52,22}

$$T(3, 8, 4, 7) = -\nu(3, 8)\delta(3, 4)\delta(7, 8) + \nu(3, 8)\delta(4, 8)\delta(3, 7) + i\int d1'd2'\nu(3, 8)G(3, 1')G(8, 2')T(1', 2', 4, 7)$$

(A3)

where $\nu$ is the bare Coulomb operator and we neglect the functional derivative $\delta T/\delta G$ in the kernel $\Xi$. The first two terms in the right-hand side of Eq. (A3) are the Hartree and exchange contributions to the $T$-matrix, whereas the last term is the correlation contribution. Making the time dependence of Eq. (A1) explicit and defining $T(3, 5, 4, 6) = -\delta(\tau_{35}^+\tau_{46}^-)\tilde{T}(x_3, x_5, x_4, x_6; \tau_{35})$, one gets

$$\chi_S(x_1, x_1', \tau_{11'})e^{-i\omega_S(x_1, x_1'; \tau_{11'})/2} = -i\int dx_3 dx_4 dx_5 dx_6 \int dt_3 dt_4 G(x_1, x_3; \tau_{13})G(x_4, x_1'; \tau_{11'})\tilde{T}(x_3, x_5, x_4, x_6; \tau_{34})\chi_S(x_6, x_5, \tau_{54})e^{\omega_S(x_6, x_5; \tau_{54})/2}$$

(A4)
where \( t_{ij} = t_i - t_j \) and \( t^*_ij = t^*_i - t_j \) with \( t^*_i = t_i + \eta (\eta \to 0^+) \) and

\[
\mathcal{T}(x_1, x_5, x_4, x_3; \tau_{34}) = \psi(x_1, x_5)\delta(\tau_{34})\delta(x_3, x_4)\delta(x_4, x_3) - \psi(x_3, x_4)\delta(x_1, x_5)\delta(x_3, x_4)
\]

\[
+ i \int dx_5 dx_8 \int dt_1 \psi(x_3, x_5)G(x_3, x_7; \tau_{37})G(x_5, x_8; \tau_{37})\mathcal{T}(x_7, x_8, x_4, x_6; \tau_{34})
\]

Using the Fourier transform \( G(t) = \int \frac{d\omega}{2\pi} G(\omega)e^{-i\omega t} \), changing variable from \( t_3 \) to \( \tau_{34} \) and taking the limit \( t_1' = t^*_1 \), we have

\[
\chi_S(x_1, x_1', 0^-) = -i \int dx_3 dx_4 dx_5 dx_6 \int d\tau_{34} \int \int \frac{d\omega}{2\pi} G(x_1, x_3; \omega' + \omega_S)G(x_4, x_1'; \omega')e^{i\omega'\tau_{34}}
\]

\[
\times \mathcal{T}(x_3, x_5, x_4, x_6; \tau_{34})\chi_S(x_6, x_5; -\tau_{34})e^{-i\omega\tau_{34}/2}
\]

Using the Lehman representation of the one-body Green’s function in the quasiparticle approximation given by Eq. (3), and multiply the left- and right-hand sides by \((e_a - e_i - \omega_S)\int dx_1 dx'_1\psi_a(x_1)\psi_i(x'_1)\), we obtain

\[
(e_a - e_i - \omega_S) \int dx_1 dx'_1\psi_a(x_1)\psi_i(x'_1)\chi_S(x_1, x_1', 0^-) = - \int dx_3 dx_4 dx_5 dx_6 \int d\tau_{34} \psi_a(x_3)\psi_i(x_4)
\]

\[
\times \left[ \Theta(t_{34})e^{i\omega\tau_{34}} + \Theta(-t_{34})e^{-i\omega\tau_{34}} \right] \mathcal{T}(x_3, x_5, x_4, x_6; \tau_{34})\chi_S(x_6, x_5; -\tau_{34})e^{-i\omega\tau_{34}/2}
\]

(7)

where \( \Theta \) is the Heaviside step function) using the fact that

\[
\Theta(\pm\tau)e^{-i\omega\tau} = \tau \frac{1}{2\pi i} \lim_{\eta \to 0^+} \int d\omega \frac{1}{\omega - \alpha \pm i\eta} e^{-i\omega \tau}
\]

(8)

For the resonant case, \( i.e., \omega_S > 0 \), we have

\[
\chi_S(x_1, x_1', \tau_1) = -e^{i\alpha|\tau_1|/2} \sum_{jb} \psi_b(x_1)\psi_j(x_1') \langle N|\hat{c}^\dagger_b|N, S\rangle \left[ \Theta(\tau_1)e^{-i\epsilon_2\tau_1} + \Theta(-\tau_1)e^{-i\epsilon_j\tau_1} \right]
\]

(9)

where \( \hat{c}^\dagger \) and \( \hat{c} \) are the usual creation and annihilation operators, respectively, and \( \langle N \rangle \) and \( \langle N, S \rangle \) are the ground state and the \( S \)th excited state, respectively, of the \( N \)-electron system. After some algebraic steps, one gets

\[
- (e_a - e_i - \omega_S) \langle N|\hat{c}^\dagger_i|N, S\rangle
\]

\[
= \sum_{jb} \langle N|\hat{c}_j^\dagger\hat{c}_b|N, S\rangle \left\{ \frac{i}{2\pi} \lim_{\eta \to 0^+} \int d\omega - \frac{1}{\omega_S - \omega + e_j + i\eta} + \frac{1}{\omega_S + \omega - e_b + i\eta} \right\}
\]

(10)

where we have defined

\[
\mathcal{T}_{ib,aj}(\tau_{34}) = \int dx_3 dx_4 dx_5 dx_6 \psi_a(x_3)\psi_j(x_4)\mathcal{T}(x_3, x_5, x_4, x_6; \tau_{34})\psi_b(x_6)\psi_i(x_5).
\]

(11)
Using the definition $X_{ia,S} = \langle N|e_i^a|N,S \rangle$, we arrive at

$$\epsilon_a - \epsilon_i - \omega_S X_{ia,S} + \sum_{jb} X_{jb,S} \langle ij|af \rangle + \sum_{jb} X_{jb,S} \tilde{T}^c_{ib,aj}(\omega_S) = 0 \quad (A12)$$

where the spectral representation of the dynamical $T$-matrix is

$$\tilde{T}^c_{ib,aj}(\omega_S) = \frac{i}{2\pi} \int d\omega \lim_{\eta \to 0} \tilde{T}^c_{ib,aj}(\omega)e^{-i\omega_\eta} \left[ \frac{1}{\omega_S - \omega + \epsilon_j + \epsilon_i + i\eta} + \frac{1}{\omega_S + \epsilon_b - \epsilon_a + i\eta} \right] \quad (A13)$$

with $\tilde{T}^c_{ib,aj} = T_{ib,aj} - \langle ib|af \rangle$ the correlation part of $T$. Equation (A12) represents a non-linear eigenvalue equation to calculate the positive excitation energies of a system, which can be rewritten as

$$\sum_{jb} A_{ia,jb}(\omega_S) X_{jb,S} = \omega_S X_{ia,S} \quad (A14)$$

with

$$A_{ia,jb}(\omega_S) = (\epsilon_a - \epsilon_i) \delta_{ij}\delta_{ab} + \langle ib|af \rangle + \tilde{T}^c_{ib,aj}(\omega_S). \quad (A15)$$

If one drops the dynamical part $\tilde{T}^c$, one ends up with the usual time-dependent Hartree-Fock (TDHF) equations. To calculate the correlation contribution, one can employ Eq. (10) in Eq. (A13), and, after integration over the frequency, one gets Eq. (22).
