\section*{Abstract}

We consider the problem of scheduling complex-valued demands over a discretized time horizon. Given a set of users, each user is associated with a set of demands representing different power consumption preferences. A demand is represented by a complex number, a time interval, and a utility value obtained if it is satisfied. At each time slot, the magnitude of the total selected demands should not exceed a given generation capacity. This naturally captures the supply constraints in alternating current (AC) electric systems. In this paper, we consider maximizing the aggregate user utility subject to power supply limits over a time horizon. We present approximation algorithms characterized by the maximum angle $\phi$ between any two complex-valued demands. More precisely, a PTAS is presented for the case $\phi \in [0, \frac{\pi}{2}]$, a bi-criteria FPTAS for $\phi \in [0, \pi - \varepsilon]$ for any polynomially small $\varepsilon$, assuming the number of time slots in the discretized time horizon is a constant. Furthermore, if the number of time slots is part of the input, we present a reduction to the real-valued unsplittable flow problem on a path with only a constant approximation ratio. Finally, we present a practical greedy algorithm for the single time slot case with an approximation ratio of $\frac{1}{2} \cos \frac{\phi}{2}$ and a running time complexity of only $O(N \log N)$, \(N\) standing for the aggregate number of user demands, which can be implemented efficiently in practice.

\textit{Keywords:} Algorithms, Scheduling, Smart Grid, Unsplittable Flow, Knapsack
1. Introduction

A key aspect of the emerging smart grid is to modulate users’ electricity consumption around the available power supply. A microgrid could run short of power due to emergency conditions, high electricity purchase price in the bulk market, or volatility of renewable sources. In such cases, consumers’ deferrable loads, such as dish washers and electric vehicles, can be scheduled according to the grid’s operational or economic conditions. This, in fact, models the day-ahead electric market at the distribution network whereby customers provide their deferrable demand preferences along with the amount they are willing to pay, and the grid operator decides the best allocation.

Although resource allocation and scheduling mechanisms have been well-studied in various systems from transportation to communication networks, the rise of the smart grid presents a new range of algorithmic problems, which are a departure from these systems. One focal difference is the presence of periodic time-varying entities (e.g., current, power, voltage) in AC electric systems, which are often expressed in terms of non-positive real, or even complex numbers. In power terminology [1], the real component of the complex number is called the active power, the imaginary is known as reactive power, and the magnitude as apparent power. For example, purely resistive appliances have positive active power and zero reactive power. Appliances and instruments with capacitive or inductive components have non-zero reactive power, depending on the phase lag with the input power. Machinery, such as in factories, has large inductors, and hence has positive power demand. On the contrary, shunt-capacitor equipped electric vehicle charging stations can generate reactive power.

We consider a variable power generation capacity over a discrete time horizon. Every user of the smart grid is associated with a set of demand preferences, wherein a demand is represented by a complex-valued number, a time interval at which it should be supplied, and a utility value obtained if it is satisfied. Some demands are inelastic (i.e., indivisible) in a sense that are either fully satisfied, or completely dropped. At each time slot, the magnitude of the total satisfied demands among all different preferences should not exceed the current net generation capacity of the grid. This captures the variation in supply constraints over time in alternating current (AC) electric systems, and allows to model the demand response management in power systems[2].

Conventionally, demands in AC systems are represented by complex numbers in the first and fourth quadrants of the complex plane. We note that our problem is invariant, when the arguments of all demands are shifted by the same angle. For convenience, we assume the demands are rotated such that one of them is aligned along the positive real axis. In realistic setting of power systems, the active power demand is positive, but the power factor (i.e., the cosine of the demand’s argument) is bounded from below by a certain threshold, which is equivalent to restricting the argument of complex-valued demands.

We present approximation algorithms characterized by the maximum angle $\phi$ between any two complex-valued demands. More precisely, we present a PTAS for the case $\phi \in [0, \frac{\pi}{2}]$, a bi-criteria FPTAS for $\phi \in [0, \pi-\varepsilon]$ for any polynomially
small $\varepsilon$, assuming the number of time slots in the discretized time horizon is constant. Furthermore, if the number of time slots is polynomial (in the input size), we present a reduction to the unsplitable flow problem on a path that adds only a constant factor to the approximation ratio. We remark that the unsplitable flow problem considers only real-valued demands which is indeed simpler than our setting. Finally, we present a practical greedy algorithm for the single time slot case with an approximation ratio of $\frac{1}{2} \cos \frac{\phi}{2}$ and a running time of $O(N \log N)$, where $N$ is the total number of complex-valued user demands, which can be implemented in real world power systems.

The paper is structured as follows. In Sec. 2 we briefly present the related works. In Sec. 3 we provide the problem definitions and notations needed. Then we present algorithms for the case of a constant number of time slots in Sec. 4, namely, a PTAS for $\phi \in [0, \frac{\pi}{2}]$ and an FPTAS for $\phi \in [0, \pi - \varepsilon]$. In Sec. 5 we present the reduction to the unsplitable flow problem for the case of a polynomial number of time slots. The proposed greedy algorithm is provided in Sec. 6. In Sec. 7 we show how to include elastic demands, i.e., demands that can be partially satisfied, along with the inelastic ones in the problem formulation. Lastly, Sec. 8 concludes this article.

2. Related work

Several recent studies consider resource allocation with inelastic demands (that is, when the decision variables are all binary). For a single time slot case, the problem studied here resembles the complex-demand knapsack problem (CKP) [3]. Let $\phi$ be the maximum angle between any pair of complex-valued demands and $N$ be the total number of these demands. A $\frac{1}{2}$-approximation was obtained [3] for the case where $0 \leq \phi \leq \frac{\pi}{2}$. On the other hand, it was shown in [4] (also [3]) that no fully polynomial-time approximation scheme (FPTAS) exists. Recently, a polynomial-time approximation scheme (PTAS), and a bi-criteria FPTAS (allowing constraint violation) for $\frac{\pi}{2} < \phi < \pi - \varepsilon$ were obtained in [5, 6]. This essentially closes the approximation gap as it is shown in [7] that when $\phi \in (\frac{\pi}{2}, \pi]$, there is no $\alpha$-approximation to CKP for any $\alpha$ with polynomial number of bits, unless P=NP. Additionally, when $\varepsilon$ is arbitrarily close to zero (i.e., $\phi \to \pi$) there is no $(\alpha, \beta)$-approximation in general for any $\alpha, \beta$ with polynomial number of bits, unless P=NP. Therefore, the PTAS and the bi-criteria FPTAS [5] are the best approximation possible for CKP. In [8], an extension of CKP was provided to handle a constant number of quadratic (and linear) constraints. A fast greedy algorithm was given in [9] for solving CKP with a constant approximation ratio that runs in $O(N \log N)$ time. A recent work [10] extends the greedy algorithm to solve the optimal power flow problem (OPF) with inelastic demands, a generalization of CKP to a networked setting including voltage constraints.

When the demands are real-valued, the problem under study (considering multiple time slots) is related to the unsplitable flow problem on a path (UFP). In UFP, each demand is associated with a unique path from a source to a sink. UFP is strongly NP-hard [11]. A Quasi-PTAS was obtained by Bansal
et al. [12]. Anagnostopoulos et al. [13] obtained a $1/(2 + \epsilon)$-approximation (where $\epsilon > 0$ is a constant). This matched the previously known approximation under the no bottleneck assumption (NBA) [14], which is the case when the largest demand is at most the smallest capacity. The UFP with bag constraints (bag-UFP) is the generalization of UFP where each user has a set of demands among which at most one is selected [15]. This problem is APX-hard even in the case of unit demands and capacities [16]. Under the NBA assumption, a $1/165$-approximation was obtained in [17], which was later improved by [15] to $1/17$. More recently, an $O(\log N/\log \log N)^{-1}$-approximation without NBA was obtained in [18]. A constant factor approximation to bag-UFP remains an interesting open question.

In this paper, we extend the complex-demand knapsack problem over a discretized time horizon, where each time slot is associated with a fixed supply limit. A user provides multiple demand preferences with their respective time window from which at most one is selected. When the number of time slots is constant, the problem generalizes CKP (see, [5]) to multiple time slots, and also extends that of [8] by considering multiple demands per user, thereby adding $n$ extra constraints, where $n$ is the number of users. Furthermore, for the case of a polynomial number of time slots, our problem is a generalization of the unsplittable flow problem on paths to accommodate complex-valued demands. Finally, we extend the greedy algorithm in [9] (for the single time slot case) to handle multiple demands per user keeping the same approximation ratio and running time.

3. Problem Definitions and Notations

In this section we formally define the complex-demand scheduling problem. Throughout this paper, we sometimes denote $\nu^R \triangleq \text{Re}(\nu)$ as the real part and $\nu^I \triangleq \text{Im}(\nu)$ as the imaginary part of a given complex number $\nu \in \mathbb{C}$. We use $|\nu|$ to denote the magnitude of $\nu$ and $\text{arg}(\nu)$ to denote the angle $\nu$ makes with the positive real axis. Unless stated otherwise, we denote $\mu_t$ (and sometimes $\mu(t)$ whenever we use subscripts for other purposes) as the $t$-th component of the vector $\mu$.

3.1. Complex-demand Scheduling Problem

Consider a discrete time horizon denoted by $T \triangleq \{1, \ldots, m\}$. At each time slot $t \in T$, the generation capacity of the power grid is denoted by $C_t \in \mathbb{R}_+$. Denote by $\mathcal{N} \triangleq \{1, \ldots, n\}$ the set of all users with cardinality $n \triangleq |\mathcal{N}|$. Each user $k \in \mathcal{N}$ declares a set of demand preferences indexed by the set $D_k$. Each demand $j \in D_k$ is defined over a time interval $T_j \subseteq T$, that is, $T_j = \{t_1, t_1 + 1, \ldots, t_2\}$ where $t_1, t_2 \in T$ and $t_1 \leq t_2$. Demand $j$ is also associated with a set of complex numbers $\{s_{k,j}(t)\}_{t \in T_j}$ where $s_{k,j}(t) \triangleq s^R_{k,j}(t) + is^I_{k,j}(t) \in \mathbb{C}$ is a complex power demand at time $t$. A positive utility $u_{k,j}$ is associated with each user demand $(k, j)$ if satisfied.
The goal is to find a solution of control variables \((x_{k,j})_{k \in \mathcal{N}, j \in D_k} \in \{0, 1\}^{\sum_{i \in \mathcal{N}} |D_i|}\) that maximizes the total utility of satisfied users subject to the generation capacity over time. More formally, we define the complex-demand scheduling problem over \(m\) discrete time slots (\(m\)-CSP) by the following integer programming problem.

\[
(m\text{-CSP}) \quad \max \sum_{k \in \mathcal{N}} \sum_{j \in D_k} u_{k,j} x_{k,j} \tag{1}
\]

subject to \[
\left| \sum_{k \in \mathcal{N}} \sum_{j \in D_k : T_j \ni t} s_{k,j}(t) \cdot x_{k,j} \right| \leq C_t, \quad \text{for all } t \in \mathcal{T} \tag{2}
\]
\[
\sum_{j \in D_k} x_{k,j} \leq 1, \quad \text{for all } k \in \mathcal{N} \tag{3}
\]
\[
x_{k,j} \in \{0, 1\}, \quad \text{for all } (k, j) \in \mathcal{I}, \tag{4}
\]

where \(\mathcal{I} = \{(k, j) : k \in \mathcal{N} \text{ and } j \in D_k\}\). Cons. \((2)\) captures the capacity limit, and Cons. \((3)\) forces at most one demand for every user to be selected. Note that \((2)\) is equivalent to a quadratic constraint

\[
\left( \sum_{k \in \mathcal{N}} \sum_{j \in D_k : T_j \ni t} \text{Re}(s_{k,j}(t)) \cdot x_{k,j} \right)^2 + \left( \sum_{k \in \mathcal{N}} \sum_{j \in D_k : T_j \ni t} \text{Im}(s_{k,j}(t)) \cdot x_{k,j} \right)^2 \leq C_t^2, \forall t \in \mathcal{T}.
\]

We consider the following assumption that are mainly needed in Sec. 4.2:

- all demands \(s_{k,j}(t)\), for \(j \in D_k\) and \(t \in T_j\), reside in the same quadrant of the complex plane.

We also assume without loss of generality that \(u_{k,j} > 0\) and \(|s_{k,j}(t)| \leq C_t\) for all \((k, j) \in \mathcal{I}\) and \(t \in \mathcal{T}\). Problem 1-CSP (i.e., \(|\mathcal{T}| = 1\)) is called the complex-demand knapsack, denoted by \(\text{CKP}\). Evidently, \(m\)-CSP is NP-complete, since the knapsack problem is its special case when we set all \(s_{k,j}^1(1) = 0, \mathcal{T} = \{1\}\), and \(|D_k| = 1\). We will write \(m\text{-CSP}[\phi_1, \phi_2]\) for the restriction of problem \(m\)-CSP subject to \(\phi_1 \leq \max_{k \in \mathcal{N}} \text{arg}(s_{k,j}(t)) \leq \phi_2\), where we assume \(\text{arg}(s_{k,j}(t)) \geq 0\) for all \((k, j) \in \mathcal{I}, t \in T_j\).

### 3.2. Approximation Algorithms

Given a solution \(x \triangleq (x_{k,j})_{k \in \mathcal{N}, j \in D_k}\), denote the total utility by \(u(x) \triangleq \sum_{k \in \mathcal{N}} \sum_{j \in D_k} u_{k,j} x_{k,j}\). We denote an optimal solution to \(m\text{-CSP}\) by \(x^*\) and \(\text{OPT} \triangleq u(x^*)\). With a slight abuse of notation, for a given subset \(S \subseteq \mathcal{N}\), we write \(u(S) \triangleq \sum_{k \in S} \sum_{j \in D_k} u_{k,j}\).

**Definition 1.** For \(\alpha \in (0, 1]\) and \(\beta \geq 1\), we define a bi-criteria \((\alpha, \beta)\)-approximation to \(m\)-CSP as a solution \(\hat{x} = (\hat{x}_{k,j})_{(k,j) \in \mathcal{I}} \in \{0, 1\}^{\mathcal{I}}\) satisfying Cons. \((3)-(4)\), and

\[
\left| \sum_{k \in \mathcal{N}} \sum_{j \in D_k : T_j \ni t} s_{k,j}(t) \cdot \hat{x}_{k,j} \right| \leq \beta \cdot C_t, \quad \text{for all } t \in \mathcal{T} \tag{5}
\]

such that \(u(\hat{x}) \geq \alpha \text{OPT}\).
In the above definition, $\alpha$ characterizes the approximation ratio between an approximate solution and the optimal solution, whereas $\beta$ characterizes the violation bound of constraints. In particular, \textit{polynomial-time approximation scheme} (PTAS) is a $(1 - \epsilon, 1)$-approximation algorithm for any $\epsilon > 0$. The running time of a PTAS is polynomial in the input size for every fixed $\epsilon$, but the exponent of the polynomial might depend on $1/\epsilon$. An even stronger notion is a \textit{fully polynomial-time approximation scheme} (FPTAS), which requires the running time to be polynomial both in input size and $1/\epsilon$. In this paper, we are interested in bi-criteria FPTAS, which is a $(1, 1 + \epsilon)$-approximation algorithm for any $\epsilon > 0$, with the running time to be polynomial in the input size and $1/\epsilon$. When $\beta = 1$, we sometimes call an $(\alpha, \beta)$-approximation an $\alpha$-approximation.

4. \textit{m-CSP} with a Constant Number of Time Slots

In this section we assume the number of time slots $|T|$ is a constant. This assumption is practical in the realistic setting, where users declare their demands on hourly basis one day ahead in the electricity market. We remark that the results in this and the next section do not require $T_j$ to be a continuous interval in $T$.

4.1. PTAS for \textit{m-CSP}[0, $\pi/2$]

Define a convex relaxation of \textit{m-CSP} (denoted by $\text{rlxCSP}$), such that Cons. (4) are replaced by $x_{k,j} \in [0, 1]$ for all $(k, j) \in I$. We define another convex relaxation that will be used in the PTAS denoted by $\text{rlxCSP}[S_1, S_0]$ which is equivalent to $\text{rlxCSP}$, subject to partial substitution such that $x_{k,j} = 1$, for all $(k, j) \in S_1$ and $x_{k,j} = 0$, for all $(k, j) \in S_0$, where $S_1, S_0 \subseteq I$ such that $S_1 \cap S_0 = \emptyset$:

\[
\begin{align*}
\text{(rlxCSP}[S_1, S_0]) \quad & \max_{x_{k,j} \in [0,1]} \sum_{k \in N} \sum_{j \in D_k} u_{k,j} x_{k,j}, \quad \text{s.t.} \\
\left( \sum_{k \in N} \sum_{j \in I_{k,j}\in T_j} s_{k,j}^R(t) \cdot x_{k,j} \right)^2 + \left( \sum_{k \in N} \sum_{j \in I_{k,j}\in T_j} s_{k,j}^I(t) \cdot x_{k,j} \right)^2 \leq C_t^2, \forall t \in T \\
\sum_{j \in D_k} x_{k,j} \leq 1, & \quad \text{for all } k \in N \\
x_{k,j} = 1, & \quad \text{for all } (k, j) \in S_1 \\
x_{k,j} = 0 & \quad \text{for all } (k, j) \in S_0.
\end{align*}
\]

The above relaxation can be solved approximately in polynomial time using standard convex programming algorithms (see, e.g., [19]). In fact, such algorithms can find a feasible solution $x^*$ to the convex relaxation such that $u(x^*) \geq \text{Opt}^* - \delta$, in time polynomial in the input size (including the bit complexity) and $\log \frac{1}{\delta}$, where $\text{Opt}^*$ is the optimal objective value of $\text{rlxCSP}[S_1, S_0]$. Notice that the value of an optimal solution to $\text{rlxCSP}[S_1, S_0]$ problem is no
worse than that of \( m \)-CSP since the feasibility region of the latter is a subset of that of the former. This, in turn, implies that \( \text{Opt}^* \geq \text{Opt} \geq \bar{u} \triangleq \max_{k,j} u_{k,j} \), and hence setting \( \delta \) to \( \epsilon \cdot \bar{u} \) assures that \( u(x^*) \geq (1 - \epsilon^2) \cdot \text{Opt}^* \).

We provide a \((1 - \epsilon, 1)\)-approximation for \( m \)-CSP\([0, \pi/2]\) in Algorithm 1, denoted by \( m \)-CSP-PTAS. The idea of \( m \)-CSP-PTAS is based on that proposed in [8, 20] with two extensions. First, we consider multiple demands per user. This in fact adds \( n \) extra constraints to that in [8, 20], and thus the rounding procedure requires further analysis. The second extension is the addition of elastic demands \( F \). We remark that [5] considers multiple inelastic demands per user for the single time slot case (denoted by CKP); however, their algorithm is based on a completely different geometric approach that is more complicated than that in [8].

Given a feasible solution \( x^* \) to \( rlx\text{CSP}[S_1, S_0] \), a restricted set of demands \( S \subseteq I \cup F \), and vectors \( c^1, c^2 \in \mathbb{R}^m_+ \), we define the following relaxation, denoted by \( \text{LP}[c^1, c^2, x^*, S] \):

\[
\max_{x_{k,j} \in [0, 1]} \sum_{k \in N} \sum_{j \in D_k} u_{k,j} x_{k,j}
\]

subject to
\[
\sum_{k \in N} \sum_{j \in D_k : t \in T} s_{k,j}^R(t) \cdot x_{k,j} \leq c^1_t, \quad \text{for all } t \in T \quad (12)
\]
\[
\sum_{k \in N} \sum_{j \in D_k : t \in T} s_{k,j}^I(t) \cdot x_{k,j} \leq c^2_t, \quad \text{for all } t \in T \quad (13)
\]
\[
\sum_{j \in D_k} x_{k,j} \leq 1, \quad \text{for all } k \in N \quad (14)
\]
\[
x_{k,j} = x^*_{k,j}, \quad \text{for all } (k, j) \in S. \quad (15)
\]

The Algorithm proceeds as follows. We guess \( S_1 \subseteq I \) to be the set of largest-utility \( \frac{8m}{\epsilon} \) inelastic demands in the optimal solution; this defines an excluded set of demands \( S_0 \subseteq I \setminus S_1 \) whose utilities exceed one of the utilities in \( S_1 \) (Step 4). For each such \( S_1 \) and \( S_0 \), we solve the convex program \( rlx\text{CSP}[S_1, S_0] \) and obtain a \((1 - \epsilon^2)\)-approximation \( x^* \) (note that the feasibility of the convex program is guaranteed by the conditions in Step 3). The real and imaginary projections over all time slots of solution \( x^* \), denoted by \( L^R, L^I \in \mathbb{R}^m_+ \), are used to define the linear program \( \text{LP}[L^R, L^I, x^*, S_1 \cup S_0] \) over the restricted set of demands \( S_1 \cup S_0 \). We solve the linear program in Step 9 and then round down the solution corresponding to demands \( (k, j) \in I \) in Step 10. Finally, we return a solution \( \hat{x} \) that attains maximum utility among all obtained solutions.

**Theorem 1.** For any fixed \( \epsilon \), Algorithm 3 obtains a \((1 - \epsilon, 1)\)-approximation in polynomial time.

We remark that a PTAS is the best approximation one can hope for, since it is shown in [3, 4] that it is NP-Hard to obtain an FPTAS for the single time slot version \((1\text{-CSP}[0, \pi/2])\).
Algorithm 1 m-CSP-PTAS\([}\{u_{k,j}, \{s_{k,j}(t)\}_{t \in T}\}_k \in \mathcal{N}, j \in D_k, (C_t)_{t \in T}, \epsilon]\)

Require: Users’ utilities and demands \(\{u_{k,j}, \{s_{k,j}(t)\}_{t \in T}\}_k \in \mathcal{N}, j \in D_k\); capacity over time \(C_t\), accuracy parameter \(\epsilon\)

Ensure: \((1 - \epsilon, 1)\)-solution \(\hat{x}\) to m-CSP\([0, \frac{\epsilon}{2}]\)

1: \(\hat{x} \leftarrow 0\)
2: for each set \(S_1 \subseteq \mathcal{I}\) such that \(|S_1| \leq \frac{8m}{\epsilon}\) do
3: \(\text{if } \sum_{(k,j) \in S_1, t \in T} s_{k,j}(t) \leq C_t\) for all \(t \in \mathcal{T}\) and \(|\{j : (k,j) \in S_1\}| \leq 1\), for all \(k \in \mathcal{N}\) then
4: \(S_0 \leftarrow \{(k,j) \in \mathcal{I} \setminus S_1 \mid u_{k,j} > \min_{(k',j') \in S_1} u_{k',j'}\}\)
5: \(x^* \leftarrow\) Solution of rlxCSP\([S_1, S_0]\) \(\text{Obtain a } (1 - \frac{\epsilon}{2})\)-approximation
6: for all \(t \in \mathcal{T}\) do
7: \(L^R_t \leftarrow \sum_{k \in \mathcal{N}} \sum_{j \in \mathcal{D}_t} s^R_{k,j}(t) \cdot x^*_{k,j}; L^1_t \leftarrow \sum_{k \in \mathcal{N}} \sum_{j \in \mathcal{D}_t} s^1_{k,j}(t) \cdot x^*_{k,j}\)
8: end for
9: \(x^{bp} \leftarrow\) Solution of LP\([L^R, L^1, x^*, S_1 \cup S_0]\]
10: \(\bar{x} \leftarrow\) \{(\bar{x}_{k,j})_{k \in \mathcal{N}, j \in \mathcal{D}_k} \mid \bar{x}_{k,j} = \lfloor x^{bp}_{k,j} \rfloor \text{ for } (k,j) \in \mathcal{I}\}
11: if \(u(\bar{x}) > u(\bar{x})\) then
12: \(\hat{x} \leftarrow \bar{x}\)
13: end if
14: end for
15: end if
16: return \(\hat{x}\)

Proof. One can easily see that the running time of Algorithm 1 is polynomial in size of the input, for any given \(\epsilon\). We now argue that the solution \(\hat{x}\) is \((1 - \epsilon)\)-approximation for m-CSP\([0, \frac{\epsilon}{2}]\). Let \(x^*\) be the optimal solution for m-CSP\([0, \frac{\epsilon}{2}]\) of utility \(\text{Opt} \triangleq u(x^*)\). Define \(S^* \triangleq \{(k,j) \in \mathcal{I} \mid x^*_{k,j} = 1\}\). By the feasibility of \(x^*\), in Step 3 the algorithm obtains

\[
u(x^*) \geq (1 - \frac{\epsilon}{2}) \cdot \text{Opt}^* \geq (1 - \frac{\epsilon}{2}) \cdot \text{Opt},
\]

where \(\text{Opt}^*\) is the optimal value of rlxCSP\([S_1, S_0]\) for some \(S_1\) equal to the highest \(\frac{8m}{\epsilon}\) utility demands in \(S^*\), and \(S_0 \cap S^* = \emptyset\). If \(|S^*| \leq \frac{8m}{\epsilon}\), then obviously \(\hat{x} = x^{bp} = x^*\) and \(u(x^{bp}) \geq (1 - \frac{\epsilon}{2})\text{Opt}\).

Now suppose \(|S^*| > \frac{8m}{\epsilon}\). Observe that \(x^*\) is feasible for LP\([L^R, L^1, x^*, S_1 \cup S_0]\) (Cons. (12)-(15) are tight when \(x^*\) is substituted). Therefore, the optimal solution \(x^{bp}\) of LP\([L^R, L^1, x^*, S_1 \cup S_0]\) satisfies

\[
u(x^{bp}) \geq u(x^*).
\]

By Lemma 1 below, LP\([L^R, L^1, x^*, S_1 \cup S_0]\) has a basic feasible solution (BFS) with at most \(4m\) fractional components, and for any fractional component \((k,j) \in \mathcal{I} \setminus (S_1 \cup S_0), u_{k,j} < \min_{(k',j') \in S_1} u_{k',j'}\),

\[
s_{k,j}(t) \leq \sum_{(k',j') \in S_1} u_{k',j'} \leq \frac{|S_1|}{|S^*|} u_{k',j'}.
\]

Therefore,
In this section, we extend this setting to the second quadrant (rounding down $x \in \mathbb{R}$ for any arbitrary small constant $\varepsilon > 0$ where the second to last inequalities follow by Eqns. (16)-(17). It remains case $|T|$ for all $k$.

L. all demands lie in the positive quadrant of the complex plane (i.e., $14)$, implying that at least $\max\{\mathbb{R}_{k,j} \leq 2m \}$. Since some components of $x^{lp}$ in Step 10 are only rounded down, Cons. (2) are also satisfied.

**Lemma 1** ([21]). Let $x$ be a basic feasible solution (BFS) for $LP[e^1, e^2, x^a, S]$. Then $x$ has at most $4m$ non-integral components.

**Remark 1.** The above proof shows that we do not need actually to solve $LP[L_R, L, x^a, S_1 \cup S_2]$; starting from $x^a$, we only need to get a BFS with the same (or better) objective value, which can be reduced to solving systems of linear equations.

**Proof.** Let $h$ be the number of users $k$ such that $\sum_{j \in D_k} x_{k,j} = 1$. By the properties of a BFS (see, e.g., [22, 23]), the number of strictly positive components in $x$ is at most $2m + h$. Furthermore, constraints (14) impose that for each $k \in \mathcal{N}$ among those $h$ users, there is a $j \in D_k$ such that $x_{k,j} > 0$. The remaining $2m$ positive variables can belong to at most $2m$ of the constraints (14), implying that at least $\max\{h - 2m, 0\}$ variables are set to 1. It follows that the total number variables taking non-integral values is at most $2m + h - \max\{h - 2m, 0\} \leq 4m$.

### 4.2. Bi-criteria FPTAS for $m$-CSP$[0, \pi - \varepsilon]$

In the previous section, we have restricted our attention to the setting where all demands lie in the positive quadrant of the complex plane (i.e., $m$-CSP$[0, \frac{\pi}{2}]$). In this section, we extend this setting to the second quadrant ($m$-CSP$[0, \pi - \varepsilon]$) for any arbitrary small constant $\varepsilon > 0$, that is, we assume $\arg(s_{k,j}(t)) \leq \pi - \varepsilon$ for all $k \in \mathcal{N}, j \in D_k, t \in T_j$. It is shown in [7] that for 1-CSP$[0, \pi]$ (the case $|T| = 1$) there is no $(\alpha, 1)$-approximation for 1-CSP$[0, \pi - \varepsilon]$ unless P=NP.
Therefore, a bi-criteria \((1, 1 + \epsilon)\) is the best approximation one can hope for. Additionally, it is shown that if \(\epsilon\) is arbitrarily close to zero, then there is no \((\alpha, \beta)\)-approximation in general for any \(\alpha, \beta\) with polynomial number of bits, unless \(P=NP\). Thus, one should expect the running time of \((1, 1 + \epsilon)\) to depend on the maximum angle \(\phi \triangleq \max_{k \in \mathcal{N}, j \in \mathcal{D}_k, t \in \mathcal{T}_j} \arg(s_{k,j}(t))\). We present below such an algorithm, which is an extension of that presented by \(\cite{5}\) for multiple time slots.

For convenience, we let \(\theta \triangleq \max\{\phi - \frac{\pi}{2}, 0\}\) (see Fig. 1 for an illustration). We present a \((1, 1 + \epsilon)\)-approximation for \(m\)-CSP\([0, \pi - \epsilon]\) in Algorithm 2, denoted by \(m\)-CSP-biFPTAS, with running time polynomial in both \(1/\epsilon\) and \(n\) (i.e., FPTAS). We assume that \(\tan \theta\) is bounded by a polynomial in \(n\); as mentioned above, without this assumption, a bi-criteria FPTAS is unlikely to exist (see \(\cite{7}\)).

Let \(\mathcal{N}_+ \triangleq \{k \in \mathcal{N} \mid s^R_{k,j}(t) \geq 0, \forall j \in \mathcal{D}_k, t \in \mathcal{T}_j\}\) and \(\mathcal{N}_- \triangleq \{k \in \mathcal{N} \mid s^R_{k,j}(t) < 0, \forall j \in \mathcal{D}_k, t \in \mathcal{T}_j\}\) be the subsets of users with demands in the first and second quadrants, respectively. Note that \(\mathcal{N}_+\) and \(\mathcal{N}_-\) partition the set of users \(\mathcal{N}\) by the assumption stated in Sec. 3. Consider any solution \(\hat{x}\) to \(m\)-CSP\([0, \pi - \epsilon]\). The basic idea of Algorithm \(m\)-CSP-biFPTAS is to enumerate the guessed total projections on real and imaginary axes of all time slots for \(\sum_{k \in \mathcal{N}_+} \sum_{j \in \mathcal{D}_k} \hat{x}_{k,j} s_{k,j}(t)\) and \(\sum_{k \in \mathcal{N}_-} \sum_{j \in \mathcal{D}_k} \hat{x}_{k,j} s_{k,j}(t)\), respectively. We can use \(\tan \theta\) to upper bound the total projections for any feasible solution \(\hat{x}\) (see Fig. 1 for a pictorial illustration) as follows, for all \(t\):

\[
\sum_{k \in \mathcal{N}_+} \sum_{j \in \mathcal{D}_k} s^R_{k,j}(t) \cdot \hat{x}_{k,j} \leq C_t, \quad \sum_{k \in \mathcal{N}_-} \sum_{j \in \mathcal{D}_k} s^R_{k,j}(t) \cdot \hat{x}_{k,j} \leq C_t \tan \theta, \\
\sum_{k \in \mathcal{N}_+} \sum_{j \in \mathcal{D}_k} s^R_{k,j}(t) \cdot \hat{x}_{k,j} \leq C_t(1 + \tan \theta) \tag{20}
\]

We then solve two separate multi-dimensional knapsack problems of dimension \(2m\) (denoted by \(2mDKP\)), to find subsets of demands that satisfy the individual guessed total projections. But since \(2mDKP\) is generally NP-hard, we need to round-up the demands to get a problem that can be solved efficiently by dynamic programming. We show that the violation of the optimal solution to the rounded problem w.r.t. to the original problem is small in \(\epsilon\).
Next, we describe the rounding in detail. First, define \( L_t \triangleq \frac{\epsilon C}{n(\tan \theta + 1)} \), for all \( t \in T \) such that the new rounded demands \( \hat{s}_{k,j}(t) \) are defined by:

\[
\hat{s}_{k,j}(t) = \frac{s_{k,j}(t)}{L_t} \cdot L_t + i \frac{s_{k,j}(t)}{L_t} \cdot L_t, \quad \text{if } s_{k,j}(t) \geq 0,
\]

\[
\hat{s}_{k,j}(t) = \frac{s_{k,j}(t)}{L_t} \cdot L_t + i \frac{s_{k,j}(t)}{L_t} \cdot L_t, \quad \text{otherwise}.
\]

(21)

For convenience, we assume that \( s_{k,j}(t) = 0 \) if \( t \notin T \). Let \( \xi_+ \in \mathbb{R}_+^m \) (and \( \xi_- \in \mathbb{R}_-^m \)), \( \zeta_+ \in \mathbb{R}_+^m \) (and \( \zeta_- \in \mathbb{R}_-^m \)) be respectively the guessed real and imaginary absolute total rounded projections of an optimal solution. Then, the possible values of \( \xi_+, \xi_-, \zeta_+ \) and \( \zeta_- \) in each component \( t \in T \) are integer multiples of \( L_t \):

\[
\xi_+(t) \in \mathcal{A}_+(t) \triangleq \left\{ 0, L_t, 2L_t, \ldots, \left[ \frac{C_t(1 + \tan \theta)}{L_t} \right] \cdot L_t \right\},
\]

\[
\xi_-(t) \in \mathcal{A}_-(t) \triangleq \left\{ 0, L_t, 2L_t, \ldots, \left[ \frac{C_t \cdot \tan \theta}{L_t} \right] \cdot L_t \right\},
\]

\[
\zeta_+(t), \zeta_-(t) \in \mathcal{B}(t) \triangleq \left\{ 0, L_t, 2L_t, \ldots, \left[ \frac{C_t}{L_t} \right] \cdot L_t \right\}.
\]

(22)

The next step is to solve the rounded instance exactly. Assume an arbitrary order on \( \mathcal{N} = \{1, \ldots, n\} \). We use recursion to define a table, with each entry \( U(k, \epsilon_1, \epsilon_2) \), \( \epsilon_1, \epsilon_2 \in \mathbb{R}_m^+ \), as the maximum utility obtained from a subset of users \( \{1, 2, \ldots, K\} \subseteq \mathcal{N} \) with demands \( \{\hat{s}_{k,j}(t)\}_{k \in \{1, \ldots, K\}, j \in D_k, t \in T} \) that can fit exactly (i.e., satisfy the capacity constraints with equality) within capacities \( \{c_1^t\}_{t=1}^m \) on the real axis and \( \{c_2^t\}_{t=1}^m \) on the imaginary axis. We denote by \( 2m\text{DKP-Exact}[\cdot] \) the algorithm for solving exactly the rounded \( 2m\text{DKP} \) by dynamic programming. We provide the detailed description of \( 2m\text{DKP-Exact}[\cdot] \) in Algorithm 3.

**Theorem 2.** Algorithm \( m\text{-CSP-}m\text{FPTAS} \) is a \((1, 1 + 4\epsilon)\)-approximation for \( m\text{-CSP}[0, \pi, \epsilon] \) and its running time is polynomial in both \( n \), \( \sum_k |D_k| \), and \( \frac{1}{\epsilon} \).

**Proof.** First, the running time is proportional to the number of guesses, upper bounded by \( (\frac{1}{2}n(\tan \theta + 1))^{O(m)} \). For each guess, \( 2m\text{DKP-Exact} \) constructs a table of size at most \( (\frac{1}{2}n(\tan \theta + 1))^{O(m)} \). Since we assumed \( \tan \theta \) is polynomial in \( n \), the total running time is polynomial in \( n \) and \( \frac{1}{\epsilon} \), if \( m = O(1) \).

To show the approximation ratio of 1, we note that \( m\text{-CSP-}m\text{FPTAS} \) enumerates over all possible rounded projections subject to the capacity constraints in \( m\text{-CSP} \) and that \( 2m\text{DKP-Exact} \) returns the exact optimal solution for each rounded problem. In particular, by Lemma 2 below one of the choices would be the rounded projection for the optimum solution \( x^* \). It remains to show that the violation of the returned solution is small in \( \epsilon \). This is given in Lemma 3 below, which shows that the solution \( \hat{x} \) to the rounded problem violates the capacity constraint by only a factor of at most \((1 + 4\epsilon)\). Both lemmas can be proved in the same way as in [3]; we include the proof below for completeness.
Algorithm 2 m-CSP-mFPTAS\([\{u_{k,j}; \{s_{k,j}(t)\}_{t \in T_j}\}_{k \in \mathcal{N}, j \in D_k}, (C_t)_{t \in T}, \epsilon]\)

Require: Users’ utilities and demands \([\{u_{k,j}; \{s_{k,j}(t)\}_{t \in T_j}\}_{k \in \mathcal{N}, j \in D_k};\) capacity over time \(C_t;\) accuracy parameter \(\epsilon\)

Ensure: \((1, 1 + 4\epsilon)\)-solution \(\tilde{x}\) to m-CSP\([0, \pi \epsilon]\]

1: \(\tilde{x} \leftarrow 0\)
2: for all \(s_{k,j}(t), k \in \mathcal{N}, j \in D_k,\) and \(t \in T_j\) do
3: \(\text{Set } \hat{s}_{k,j}(t) \leftarrow \hat{s}_{k,j}(t) + R_{k,j}(t)\) as defined by \([21]\)
4: end for
5: for all \(\xi_+ \in \prod_{t \in \mathcal{T}} A_+(t), \xi_- \in \prod_{t \in \mathcal{T}} A_-(t), \zeta_+, \zeta_- \in \prod_{t \in \mathcal{T}} B(t)\) do
6: if \((\xi_+(t) - \xi_-(t))^2 + (\zeta_+(t) + \zeta_-(t))^2 \leq (1 + 2\epsilon)^2C_t^2\) for all \(t \in \mathcal{T}\) then
7: \(y_+ \leftarrow 2m\text{DKP-Exact}\left(\{u_{k,j}; (\hat{s}_{k,j}(t)/L_t)\}_{k \in \mathcal{N}, j \in D_k}, (\xi_+(t)/L_t)\}_{t}, (\zeta_+(t)/L_t)\}_{t}\right)\)
8: \(y_- \leftarrow 2m\text{DKP-Exact}\left(\{u_{k,j}; (\hat{s}_{k,j}(t)/L_t)\}_{k \in \mathcal{N}, j \in D_k}, (\xi_-(t)/L_t)\}_{t}, (\zeta_-(t)/L_t)\}_{t}\right)\)
9: if \(u(y_+ + y_-) > u(\tilde{x})\) then
10: \(\tilde{x} \leftarrow y_+ + y_-\)
11: end if
12: end if
13: end for
14: return \(\tilde{x}\)

---

Algorithm 3 2m\text{DKP-Exact}\([\{u_{k,j}; \{s_{k,j}(t)\}_{t \in T_j}\}_{k \in \mathcal{W}, j \in D_k}, (c^1_t)_{t \in \mathcal{T}}, (c^2_t)_{t \in \mathcal{T}}]\)

Require: Utilities, and rounded demands of a restricted set of users \(\mathcal{W} \subseteq \mathcal{N}, \) \([\{u_{k,j}; \{s_{k,j}(t)\}_{t \in T_j}\}_{k \in \mathcal{N}, j \in D_k};\) integer capacity vectors \((c^1_t)_{t \in \mathcal{T}}, (c^2_t)_{t \in \mathcal{T}}\)

Ensure: A utility-maximizing optimal binary vector \(y\) subject to the capacity constraints defined by \(c^1_t, c^2_t\)

1: Create a table of size \(|\mathcal{W}| \cdot \prod_d (c^1_d + 1) \cdot (c^2_d + 1)\), with each entry \(U(k, c^1, c^2)\) according to:

\[
U(1, c^1, c^2) \triangleq \max_{j \in \mathcal{D}_1} \left\{ u_{k,j} \right\} R^1_{s_{k,j}}(t) = c^1, \quad s^2_{k,j}(t) = c^2, \quad \forall t \}
\]

\[
U(k, c^1, c^2) \triangleq \max_{j \in \mathcal{D}_k} \left\{ \max_{j \in \mathcal{D}_k} \{ u_{k,j} \} + U(k-1, (c^1_d - s_{k,j}(t))_t, (c^2_d - s_{k,j}(t))_t) \} \right\} U(k-1, c^1, c^2) \}
\]

\[
U(k, c^1, c^2) \triangleq -\infty \text{ for all } c^1, c^2, (c^1, c^2) \in \mathbb{R}_+^{d_m}
\]

2: Compute the corresponding binary vector \(y(k, c^1, c^2)\) according to the computations in step \([\mathbb{I}]\)
3: return \(y(|\mathcal{W}|, c^1, c^2)\).

---

For any binary vector \(x\) feasible for \((m\text{-CSP})\), let us write for brevity

\[
P_{+1}(x) \triangleq \sum_{k \in \mathcal{N}, j \in \mathcal{D}_k} \sum_{t \in \mathcal{T}_j} x_{k,j}R_{s_{k,j}}(t), \quad P_{-1}(x) \triangleq \sum_{k \in \mathcal{N}, j \in \mathcal{D}_k} \sum_{t \in \mathcal{T}_j} -x_{k,j}R_{s_{k,j}}(t),
\]

and \(P_{+1}(x) \triangleq \sum_{k \in \mathcal{N}, j \in \mathcal{D}_k} \sum_{t \in \mathcal{T}_j} x_{k,j}s_{k,j}(t).\)
Also, write

$$\hat{P}_{+,t}(x) \triangleq \sum_{k \in N_+} \sum_{j \in D_k : t \in T_j} x_{k,j} \hat{s}_{k,j}^R(t), \quad \hat{P}_{-,t}(x) \triangleq \sum_{k \in N_-} \sum_{j \in D_k : t \in T_j} -x_{k,j} \hat{s}_{k,j}^R(t),$$

and

$$\hat{P}_{I,t}(x) \triangleq \sum_{k \in N} \sum_{j \in D_k : t \in T_j} x_{k,j} \hat{s}_{k,j}^2(t).$$

Using the fact that $\ell \leq \tau \frac{t}{\epsilon^2} \leq \ell + \tau$ for any $\ell, \tau$ such that $\tau > 0$, and that $\sum_{j \in D_k} x_{k,j} \leq 1$ by (3), we have

$$\hat{P}_{+,t}(x) = \sum_{k \in N_+} \sum_{j \in D_k : t \in T_j} x_{k,j} \hat{s}_{k,j}^R(t) \leq \sum_{k \in N_+} \sum_{j \in D_k : t \in T_j} x_{k,j} (\hat{s}_{k,j}^R(t) + L_t) = P_{+,t}(x) + nL_t.$$

The same bound holds for $\hat{P}_{-,t}$ and $\hat{P}_{I,t}$:

$$\max\{\hat{P}_{+,t}(\tilde{x}) - nL_t, 0\} \leq P_{+,t}(x) \leq \hat{P}_{+,t}(\tilde{x}), \quad \max\{\hat{P}_{-,t}(\tilde{x}) - nL_t, 0\} \leq P_{-,t}(x) \leq \hat{P}_{-,t}(\tilde{x}),$$

$$\max\{\hat{P}_{I,t}(\tilde{x}) - nL_t, 0\} \leq P_{I,t}(x) \leq \hat{P}_{I,t}(\tilde{x}).$$

(23)

**Lemma 2.** For any feasible solution $x$ to $m$-CSP $[0, \pi, \epsilon]$, we have

$$\left| \sum_{k \in N} \sum_{j \in D_k : t \in T_j} x_{k,j} \hat{s}_{k,j}(t) \right| \leq (1 + 2\epsilon) C_t \quad \text{for all } t \in T.$$

**Proof.** Using (20) and (23), for all $t \in T$,

$$\left( \sum_{k \in N} \sum_{j \in D_k : t \in T_j} x_{k,j} \hat{s}_{k,j}^R(t) \right)^2 + \left( \sum_{k \in N} \sum_{j \in D_k : t \in T_j} x_{k,j} \hat{s}_{k,j}^2(t) \right)^2$$

$$= \left( \hat{P}_{+,t}(x) - \hat{P}_{-,t}(x) \right)^2 + \hat{P}_{I,t}^2(x)$$

$$= \hat{P}_{+,t}^2(x) + \hat{P}_{-,t}^2(x) - 2 \hat{P}_{+,t}(x) \hat{P}_{-,t}(x) + \hat{P}_{I,t}^2(x)$$

$$\leq (P_{+,t}(x) + nL_t)^2 + (P_{-,t}(x) + nL_t)^2 - 2P_{+,t}(x)P_{-,t}(x) + (P_{I,t}(x) + nL_t)^2$$

$$= (P_{+,t}(x) - P_{-,t}(x))^2 + \hat{P}_{I,t}^2(x) + 2nL_t(P_{+,t}(x) + P_{-,t}(x) + P_{I,t}(x)) + 3n^2L_t^2$$

$$= \left( \sum_{k \in N} \sum_{j \in D_k : t \in T_j} x_{k,j} \hat{s}_{k,j}(t) \right)^2 + \left( \sum_{k \in N} \sum_{j \in D_k : t \in T_j} x_{k,j} \hat{s}_{k,j}(t) \right)^2$$

$$+ 2nL_t \left( \sum_{k \in N} \sum_{j \in D_k : t \in T_j} x_{k,j} |\hat{s}_{k,j}^R(t)| + \sum_{k \in N} \sum_{j \in D_k : t \in T_j} x_{k,j} \hat{s}_{k,j}(t) \right) + 3n^2L_t^2$$

$$\leq C_t^2 + 4nL_t(\tan \theta + 1)C_t + 3n^2L_t^2 = C_t^2 + 4\epsilon C_t^2 + 3\epsilon^2 C_t^2 / (1 + \tan \theta)^2$$

$$\leq C_t^2 (1 + 4\epsilon + 3\epsilon^2) \leq C_t^2 (1 + 2\epsilon)^2.$$
Lemma 3. Let $\hat{x}$ be the solution returned by m-CSP-FPTAS. Then,

$$\left| \sum_{k \in N, j \in D_k} \sum_{t \in T_j} \hat{x}_{k,j} \hat{s}_{k,j}(t) \right| \leq (1 + 4\epsilon) C_t \quad \text{for all } t \in T.$$

Proof. As in the proof of Lemma 2 for all $t \in T$,

$$\left( \sum_{k \in N, j \in D_k} \sum_{t \in T_j} \hat{x}_{k,j} \hat{s}_{k,j}(t) \right)^2 + \left( \sum_{k \in N, j \in D_k} \sum_{t \in T_j} \hat{x}_{k,j} \hat{s}_{k,j}(t) \right)^2 = (P_{+,t}(\hat{x}) - P_{-,t}(\hat{x}))^2 + P_{t,t}^2(\hat{x})$$

$$= P_{+,t}^2(\hat{x}) + P_{-,t}^2(\hat{x}) - 2P_{+,t}(\hat{x})P_{-,t}(\hat{x}) + P_{t,t}^2(\hat{x}). \quad (24)$$

If both $\hat{P}_{+,t}(\hat{x})$ and $\hat{P}_{-,t}(\hat{x})$ are less than $nL_t$, then the R.H.S. of (24) can be bounded by

$$\hat{P}_{+,t}^2(\hat{x}) + \hat{P}_{-,t}^2(\hat{x}) \leq \hat{P}_{+,t}^2(\hat{x}) + \hat{P}_{-,t}^2(\hat{x}) - 2\hat{P}_{+,t}(\hat{x})\hat{P}_{-,t}(\hat{x}) + 2n^2 L_t^2 + \hat{P}_{t,t}^2(\hat{x})$$

$$= (\hat{P}_{+,t}(\hat{x}) - \hat{P}_{-,t}(\hat{x}))^2 + \hat{P}_{t,t}^2(\hat{x}) + 2n^2 L_t^2. \quad (25)$$

Otherwise, we bound the R.H.S. of Eqn. (24) by

$$\hat{P}_{+,t}^2(\hat{x}) + \hat{P}_{-,t}^2(\hat{x}) - 2(\hat{P}_{+,t}(\hat{x}) - nL_t)(\hat{P}_{-,t}(\hat{x}) - nL_t) + \hat{P}_{t,t}^2(\hat{x})$$

$$= (\hat{P}_{+,t}(\hat{x}) - \hat{P}_{-,t}(\hat{x}))^2 + \hat{P}_{t,t}^2(\hat{x}) - 2n^2 L_t^2. \quad (26)$$

Since $\hat{x} = y_+ + y_-$ is obtained from feasible solutions $y_+$ and $y_-$ to $2m$DPK-Exact$\left\{ \{u_{k,j}, (\hat{s}_{k,j}(t)/L_t)\}_{t \in T}, (\hat{\xi}(t)/L_t)_{t \in T} \right\}$ and $2m$DPK-Exact$\left\{ \{u_{k,j}, -(\hat{s}_{k,j}(t)/L_t)\}_{t \in T}, (\hat{\xi}(t)/L_t)_{t \in T} \right\}$, respectively, and $\hat{\xi}_+, \hat{\xi}_-, \hat{\xi}_+, \hat{\xi}_-$ satisfy the condition in Step 3 of Algorithm 2 it follows from (24)-(26) that

$$\left( \sum_{k \in N, j \in D_k} \sum_{t \in T_j} \hat{x}_{k,j} \hat{s}_{k,j}(t) \right)^2 + \left( \sum_{k \in N, j \in D_k} \sum_{t \in T_j} \hat{x}_{k,j} \hat{s}_{k,j}(t) \right)^2 \leq \left( \sum_{k \in N, j \in D_k} \sum_{t \in T_j} \hat{x}_{k,j} \hat{s}_{k,j}(t) \right)^2 + \left( \sum_{k \in N, j \in D_k} \sum_{t \in T_j} \hat{x}_{k,j} \hat{s}_{k,j}(t) \right)^2$$

$$+ 2nL_t \sum_{k \in N, j \in D_k} \sum_{t \in T_j} \hat{x}_{k,j} \hat{s}_{k,j}(t) + 2n^2 L_t^2$$

$$= (\hat{\xi}_+(t) - \hat{\xi}_-(t))^2 + (\hat{\xi}_+(t) + \hat{\xi}_-(t))^2 + 2nL_t(\hat{\xi}_+(t) + \hat{\xi}_-(t)) + 2n^2 L_t^2$$

$$\leq \left( (1 + 2\epsilon)^2 C_t^2 + 4n L_t \frac{\epsilon C_t}{n(\tan \theta + 1)}(1 + \tan \theta) C_t + 2n^2 \frac{\epsilon^2 C_t^2}{n^2(\tan \theta + 1)^2} \right)$$

$$\leq \left( (1 + 2\epsilon)^2 + 4\epsilon + 2\epsilon^2 \right) C_t^2 \leq (1 + 4\epsilon)^2 C_t^2.$$

5. m-CSP[0, $\frac{\pi}{2}$] with Polynomial number of Time Slots

In this section, we extend our results to polynomial number of time slots $|T|$. We assume herein that all demands lie in the first quadrant of the complex plane (i.e., $\phi \triangleq \max_k \text{arg}(s_{k,j}(t)) \leq \frac{\pi}{2}$ for all $t \in T$). We provide a reduction to the unsplittable flow
problem on a path with bag constraints (bag-UFP) for which recent approximation algorithms are developed in the literature (see, e.g., [15][24][17]). We remark that bag-UFP considers only real-valued demands, whereas in m-CSP demands are complex-valued. We will show that such reduction will increase the approximation ratio of bag-UFP by a constant factor of \( \cos \frac{\phi}{2} \), where \( \phi \leq \frac{\pi}{2} \) is the maximum argument of any demand. We will need the following further assumption to accommodate the setting of bag-UFP:

- all demands are constant over time: \( s_{k,j}(t) = s_{k,j}(t') \) for any \( t, t' \in T_j \). To simplify notation, let \( s_{k,j} \) denote the unique demand over all time steps \( T_j \).

For convenience, we shall refer to the problem as \( m\text{-CSP}' \) when restricted with the above assumption. When all demands in \( m\text{-CSP}' \) are real-valued, the problem is called bag-UFP. We can approximate an instance of \( m\text{-CSP}' \) by an instance of (bag-UFP) defined as follows:

\[
\text{(bag-UFP)} \quad \max_{x_{k,j} \in \{0,1\}} \sum_{k \in \mathcal{N}} \sum_{j \in D_k} u_{k,j} x_{k,j} \quad \text{s.t.} \quad \sum_{k \in \mathcal{N}} \sum_{j \in D_k, t \in T_j} |s_{k,j}| x_{k,j} \leq C_t, \quad \text{for all } t \in \mathcal{T} \tag{27}
\]

Note that the absolute of the sum in Cons. (2) is replaced in bag-UFP by the sum of the absolutes in Cons. (27). Thus all demands in bag-UFP are real-valued.

We denote by \( m\text{-CSP}'^* \) (resp., \( \text{bag-UFP}^* \)) the linear relaxation of \( m\text{-CSP}' \) (resp., bag-UFP), that is, when \( x_{k,j} \in [0,1] \) for all \( k \in \mathcal{N}, j \in D_k \). Let \( \text{Opt} \) and \( \text{Opt}^* \) be the optimal objective values of \( m\text{-CSP}' \) and bag-UFP respectively. Also denote by \( \psi \) and \( \psi^* \) the optimal objective value of \( m\text{-CSP}'^* \) and bag-UFP* respectively.

We will show in Lemma 4 and Theorem 3 below that one can use the algorithms developed for bag-UFP with bounded integrality gap to obtain approximate solutions to \( m\text{-CSP}'[0, \frac{\pi}{2}] \).

**Lemma 4.** Given a solution \( \bar{x} \in [0,1]^{|\mathcal{T}|} \) to bag-UFP such that \( u(\bar{x}) \geq \psi \cdot \text{Opt}^* \), \( \psi \in [0,1] \), then \( \bar{x} \) is feasible for \( m\text{-CSP}'[0, \frac{\pi}{2}] \) and \( u(\bar{x}) \geq \psi \cos \frac{\phi}{2} \cdot \text{Opt} \).

**Proof.** Let \((x^*_{k,j})_{k \in \mathcal{N}, j \in D_k}\) be an optimal solution for \( m\text{-CSP}'^* \). Lemma 5 below implies that

\[
\cos \frac{\phi}{2} \sum_{k \in \mathcal{N}} \sum_{j \in D_k, t \in T_j} |s_{k,j}| x^*_{k,j} \leq \sum_{k \in \mathcal{N}} \sum_{j \in D_k, t \in T_j} s_{k,j} x^*_{k,j} \leq C_t \quad \forall t \in \mathcal{T}.
\]

According to the above inequality, we can construct a feasible solution \((\tilde{x}_{k,j})_{k \in \mathcal{N}, j \in D_k}\) to bag-UFP* defined by \( \tilde{x}_{k,j} = \cos \frac{\phi}{2} \cdot x^*_{k,j} \). By the feasibility of \((\tilde{x}_{k,j})_{k \in \mathcal{N}, j \in D_k}\),

\[
\text{Opt}^* \geq \sum_{k \in \mathcal{N}} \sum_{j \in D_k} u_{k,j} \tilde{x}_{k,j} = \cos \frac{\phi}{2} \cdot \sum_{k \in \mathcal{N}} \sum_{j \in D_k} u_{k,j} x^*_{k,j} = \cos \frac{\phi}{2} \cdot \text{Opt}^*.
\]

Therefore, \( u(\tilde{x}) \geq \psi \cdot \text{Opt}^* \geq \psi \cdot \cos \frac{\phi}{2} \cdot \text{Opt}^* \geq \psi \cos \frac{\phi}{2} \cdot \text{Opt} \).

It remains to show that \( \tilde{x} \) is feasible for \( m\text{-CSP}' \), which follows readily from the triangular inequality:

\[
\sum_{k \in \mathcal{N}} \sum_{j \in D_k, t \in T_j} s_{k,j} \tilde{x}_{k,j} \leq \sum_{k \in D_k \in D_k, t \in T_j} |s_{k,j}| \tilde{x}_{k,j} \leq C_t \quad \forall t \in \mathcal{T}.
\]
Lemma 5 ([9]). Given a set of vectors \( \{d_i \in \mathbb{R}^2\}_{i=1}^n \), then \( \frac{\sum_{i=1}^n \|d_i\|}{\sum_{i=1}^n d_i} \leq \sec \frac{\theta}{2} \), where \( \theta \) is the maximum angle between any pair of vectors \( \{d_i \in \mathbb{R}^2\}_{i=1}^n \) and \( 0 \leq \theta \leq \frac{\pi}{2} \).

For completeness, we provide the proof in the appendix.

We can apply Lemma 4 using the recent LP-based algorithm by Grandoni et al. [15] to obtain the following result.

Theorem 3. There exists an \( (\Omega(\log \log n/\log n), 1)) \)-approximation for \( m\text{-CSP}'[0, \frac{\pi}{2}] \). Additionally, if all demands have the same utility, we obtain \( (\Omega(1), 1)) \)-approximation.

Prior work has addressed an important restriction of UFP (also bag-UFP) called the no bottleneck assumption (NBA), namely, \( \max_{k \in N, j \in D_k} |s_{k,j}| \leq C_{\text{min}} \triangleq \min_{t \in T} C_t \), that is, the largest demand is at most the smallest capacity over all time slots. Define the bottleneck time of demand \((k, j)\) by \( b_{k,j} \triangleq \min_{t \in T} C_t \). Given a constant \( \delta \in [0, 1] \), we call a demand \((k, j)\) \( \delta \)-small if \( |s_{k,j}| \leq \delta C_{b_{k,j}} \), otherwise we call it \( \delta \)-large.

We remark that the NBA assumption naturally holds in smart grids since individual demands are typically much smaller than the generation capacity over all time slots. In the following, we show that there exists an \( (\Omega(1), 1)) \)-approximation for \( m\text{-CSP}'[0, \frac{\pi}{2}] \) under NBA. This is achieved by splitting demands to \( \delta \)-small and \( \delta \)-large and solving each instance separately then taking the maximum utility solution. The next lemma is an extension to an earlier work by Chakrabarti et al. [24] (to accommodate complex-valued demands) used to derive a dynamic program that approximates \( \delta \)-large demands.

Lemma 6. The number of \( \delta \)-large demands that cross any time slot in any feasible solution is at most \( 2\lfloor \frac{1}{2 \pi} \cdot \sec \frac{\theta}{2} \rfloor \).

Proof. Given a feasible solution \( \hat{x} \), let \( S \triangleq \{(k, j) \in I \mid \hat{x}_{k,j} = 1, s_{k,j} > \delta b_{k,j}\} \) be the set of indices of \( \delta \)-large demands. Consider any time slot \( t \), let \( S_t \triangleq \{(k, j) \in S \mid t \in T_j\} \) be the set of demands that cross time \( t \). Then we partition \( S_t \) to the sets \( S_t^L \) and \( S_t^R \), such that \( S_t^L \) (resp., \( S_t^R \)) contains demands with bottleneck time slot on the left (resp., right) of \( t \). We show that \( |S_t^L| \leq \lfloor \frac{1}{2 \pi} \cdot \sec \frac{\theta}{2} \rfloor \), and a similar argument shows the same bound for \( |S_t^R| \).

Let \( B \) be the set of bottleneck time slots for demands in \( S_t^L \). Now let \( t' \in B \) be the rightmost bottleneck time slot in \( B \). Since \( t' \) is the bottleneck of some \( \delta \)-large demand \((k, j)\), i.e., \( \delta C_{t'} < |s_{k,j}| \), and by the NBA assumption, \( |s_{k,j}| \leq C_{\text{min}} \); it follows that \( C_{t'} < \frac{C_{\text{min}}}{2 \pi} \). Because \( t' \) is the rightmost time slot in \( B \), all demands in \( S_t^L \) pass through \( t' \), therefore \( \sum_{(k, j) \in S_t^L} s_{k,j} \leq C_{t'} \). Since all demands \((k, j) \in S_t^L \) are \( \delta \)-large, \( |s_{k,j}| > \delta C_{b_{k,j}} \geq C_{\text{min}} \). Therefore, using Lemma 5

\[
\delta C_{\text{min}} |S_t^L| < \sum_{(k, j) \in S_t^L} |s_{k,j}| \leq \sec \frac{\theta}{2} \sum_{(k, j) \in S_t^L} s_{k,j} \leq \sec \frac{\theta}{2} \cdot C_{t'} < \sec \frac{\theta}{2} \cdot \frac{1}{2 \pi} C_{\text{min}}.
\]

This gives \( |S_t^L| \leq \lfloor \frac{1}{2 \pi} \cdot \sec \frac{\theta}{2} \rfloor \).

Theorem 4. Under the NBA assumption, there exists an \( (\Omega(1), 1)) \)-approximation for \( m\text{-CSP}'[0, \frac{\pi}{2}] \). The running time is \( O(n^2) \).

Proof. We set \( \delta = \frac{1}{2} \). For small demands, Chakaravarthy et al. [24] present a primal-dual \( \frac{1}{2} \)-approximation algorithm for bag-UFP that runs in \( O(n^2) \). By Lemma 4 this algorithm is also \( \frac{1}{2} \cos \frac{\theta}{2} \)-approximation to \( m\text{-CSP}' \) with small demands. Large
demands can be handled via a simple reduction to the weighted job interval selection problem proposed in [17] (i.e., restrict selected demands to be disjoint). By Lemma 6 we loose a factor of \(8\sec \frac{\phi}{2}\), then we apply the 2-approximation by Bar-Noy et al. [26] which runs in \(O(n \log n)\). Hence we obtain a \((\frac{1}{25} \cos \frac{\phi}{2}, 1)\)-approximation that runs in \(O(n^2)\).

6. Practical Greedy Approximation for 1-CSP[0, \(\frac{\pi}{2}\)]

In this section we give a practical greedy constant-factor approximation algorithm, presented in Algorithm 4 and denoted by 1-CSP-Greedy, for the single time slot case (1-CSP[0, \(\frac{\pi}{2}\)]) where \(|\mathcal{T}| = 1\). Despite the theoretical value of the PTAS and FPTAS presented in [5] (that are generalized in Sec. 4), the running time is quite large and hence impractical for real world applications. Algorithm 1-CSP-Greedy, on the other hand, achieves \((\frac{1}{25} \cos \frac{\phi}{2}, 1)\)-approximation in \(O(N \log N)\) time, where \(N \triangleq \sum_{k \in \mathcal{N}} |D_k|\). This result can be derived directly by combining Lemma 4 (restricted to the case \(|\mathcal{T}| = 1\)) with the known analysis of the greedy algorithm for the multiple-choice Knapsack problem [27] and its connection to the LP relaxation. However, we include the proof here for completeness. Note that such a simple greedy algorithm can be used to provide a fast heuristic for practical settings when considering multiple time slots. For instance, in the setting where users arrive online, 1-CSP-Greedy could be applied to each time slot, after reducing the capacity by the magnitude of demands consumed in previous time slots.

Consider the simplified version of \(m\)-CSP denoted by 1-CSP where \(|\mathcal{T}| = 1\):

\[
\text{(1-CSP)} \quad \max \sum_{k \in \mathcal{N}} \sum_{j \in D_k} u_{k,j} x_{k,j} \tag{29}
\]

subject to

\[
\left| \sum_{k \in \mathcal{N}} \sum_{j \in D_k} s_{k,j} x_{k,j} \right| \leq C \tag{30}
\]

\[
\sum_{j \in D_k} x_{k,j} \leq 1, \quad \text{for all } k \in \mathcal{N} \tag{31}
\]

\[
x_{k,j} \in \{0, 1\} \text{ for all } (k, j) \in \mathcal{I}. \tag{32}
\]

For convenience, we add a dummy demand to each set \(D_k\), for each user \(k \in \mathcal{N}\) with utility of 0 and demand of \(s_{k,0} = 0\). This is to guarantee that a solution to 1-CSP problem contains exactly one demand from each set \(D_k\) for every user \(k \in \mathcal{N}\). Note that this change does not affect the 1-CSP problem.

If a user’s complex-valued power demand is substituted in (1-CSP) by its real-valued magnitude, the inequality constraint (31) is transformed into an equality constraint and the binary decision variables \(x_{k,j}\) are relaxed such that they take non-negative real values (i.e., \((x_{k,j})_{k \in \mathcal{N}, j \in D_k} \in [0, 1][\mathcal{I}]\)), the following linear programming (LP) problem is obtained.
\[
\text{(Rx1-CSP)} \quad \max \sum_{k \in \mathcal{N}} \sum_{j \in D_k} u_{k,j} x_{k,j} \tag{33}
\]

subject to
\[
\sum_{k \in \mathcal{N}} \sum_{j \in D_k} s_{k,j} \cdot x_{k,j} \leq C \tag{34}
\]
\[
\sum_{j \in D_k} x_{k,j} = 1, \quad \text{for all } k \in \mathcal{N} \tag{35}
\]
\[
x_{k,j} \in [0, 1] \text{ for all } (k, j) \in \mathcal{I}. \tag{36}
\]

We make use of the following statement.

**Proposition 1 ([28, 27, 29]).** (i) If two demands \( j, h \in D_k \) belonging to the same set \( D_k \), for \( k \in \mathcal{N} \), with \( |s_{k,j}| \leq |s_{k,h}| \) satisfy
\[
u_{k,j} \geq u_{k,h},
\]
then an optimal solution to \( (1-CSP) \) with \( x_{k,h} = 0 \) exists.

(ii) If two demands \( j, h \in D_k \) belonging to the same set \( D_k \), for \( k \in \mathcal{N} \), with \( |s_{k,j}| \leq |s_{k,h}| \) satisfy
\[
u_{k,j} \leq \frac{u_{k,h}}{|s_{k,j}|},
\]
then an optimal solution to Rx1-CSP with \( x_{k,j} = 0 \) exists.

(iii) If some demands \( j, h, l \in D_k \), \( k \in \mathcal{N} \) with \( |s_{k,j}| < |s_{k,h}| < |s_{k,l}| \), \( u_{k,j} < u_{k,h} < u_{k,l} \), and
\[
u_{k,j}/|s_{k,j}| > \nu_{k,h}/|s_{k,h}| > \nu_{k,l}/|s_{k,l}|
\]
satisfy
\[
u_{k,h} - \nu_{k,j} \leq \frac{u_{k,l} - u_{k,h}}{|s_{k,j}| - |s_{k,h}|},
\]
then an optimal solution to Rx1-CSP with \( x_{k,h} = 0 \) exists.

The above proposition implies that, without losing all optimal solutions to Rx1-CSP, we can preprocess the demands of each set \( D_k \), \( k \in \mathcal{N} \), to obtain a corresponding new set \( R_k \subseteq D_k \) that satisfies:

\[
|s_{k,1}| \leq |s_{k,2}| \leq \ldots \leq |s_{k,r_k}|, \tag{37}
\]
\[
|u_{k,1}| \leq |u_{k,2}| \leq \ldots \leq |u_{k,r_k}|, \tag{38}
\]
\[
\frac{u_{k,1}}{|s_{k,1}|} > \frac{u_{k,2}}{|s_{k,2}|} > \ldots > \frac{u_{k,r_k}}{|s_{k,r_k}|}, \tag{39}
\]
\[
\frac{u_{k,2} - u_{k,1}}{|s_{k,2}| - |s_{k,1}|} > \frac{u_{k,3} - u_{k,2}}{|s_{k,3}| - |s_{k,2}|} > \ldots > \frac{u_{k,r_k} - u_{k,r_k-1}}{|s_{k,r_k}| - |s_{k,r_k-1}|}. \tag{40}
\]

Observe that this reduction requires only \( O(\sum_{k \in \mathcal{N}} |D_k| \log |D_k|) \) time, as it can be done by sorting each \( D_k \) followed by a linear scan to remove the demands that do not appear in the optimal solution.

In [27] (see also [20, Chapter 11]), it was also proved that the LP optimal solution to Rx1-CSP problem may be found by a greedy algorithm which starts by finding the sets \( R_k \) above. Assume the ordering \( |s_{k,1}| \leq |s_{k,2}| \leq \ldots \leq |s_{k,r_k}| \) in \( R_k \), where \( r_k = |R_k| \). Initially, the algorithm selects the dummy demand \( s_{k,0} \) for each customer and sets the corresponding decision variables to 1. Next, the greedy algorithm constructs a
new set $E$ by combining all the sets $R_k$, $k \in \mathcal{N}$ and setting $\tilde{u}_{k,j} = u_{k,j} - u_{k,j-1}$ and $|\tilde{s}_{k,j}| = |s_{k,j}| - |s_{k,j-1}|$ for $j = 1, \ldots, r_k$. After sorting entries in $E$ by their efficiency, defined as $\frac{\tilde{s}_{k,j}}{|\tilde{s}_{k,j}|}$ in non-increasing order, the greedy execution continues by selecting demands in the aforementioned sorted considering the capacity $C$. Each time an item $(k, j)$ is selected from set $E$, we assign $\tilde{x}_{k,j} \leftarrow 1$, $\tilde{x}_{k,j-1} \leftarrow 0$ and $\tau = \tau + |\tilde{s}_{k,j}|$, where the initial value of $\tau$ is 0. Assume at some iteration adding the next item $(k', j')$ to the current solution vector $\tilde{x}$ causes capacity violation, that is

$$\tau \leq C \text{ and } \tau + |\tilde{s}_{k',j'}| > C. \quad (41)$$

The greedy execution is stopped at this point and the remaining capacity $C - \tau$ is occupied by the corresponding fractional part of the $(k', j')$ item’s power demand and the item’s $(k', j' - 1)$ decision variable is set as follows:

$$\tilde{x}_{k',j'} = \frac{C - \tau}{|\tilde{s}_{k',j'}|} \quad \text{and} \quad \tilde{x}_{k',j'-1} = 1 - \tilde{x}_{k',j'} \quad \text{where} \quad k' \in \mathcal{N}, j' \in R_{k'}.$$  

In [28, 27], it was shown that this greedy strategy indeed produces an optimal solution to RX1-CSP problem containing at most two fractional variables that belong to adjacent users in the sorted set $R_{k'}$ as given above. Note that algorithm 1-CSP-Greedy is almost the same as this greedy algorithm algorithm described above, except that we drop the fractional values.

**Theorem 5.** Algorithm 1-CSP-Greedy is $(\frac{1}{2} \cos \frac{\phi}{2}, 1)$-approximation for 1-CSP[0, $\frac{\pi}{2}$]. The running time is $O(N \log N)$.

**Proof.**

Let $S^* \subseteq \mathcal{I}$ be an optimal solution of (1-CSP), and denote by $\text{Opt}$ and $\text{Opt}^*$ the optimal objective values of (1-CSP) and (RX1-CSP), respectively. Denote by $E_0 = E \setminus \{(k', j'), (k', j' - 1)\}$, and let

$$\hat{p} \triangleq \sum_{(k,j) \in E_0} u_{k,j} \tilde{x}_{k,j} \quad \text{and} \quad u_{\max} \triangleq \max_{j \in R_k, k \in \mathcal{N}} \{u_{k,j}\},$$

where $\tilde{x}$ is as defined in the algorithm. For the optimal solution to RX1-CSP problem we get

$$\text{Opt}^* = \hat{p} + \sum_{(k,j) \in S^*} u_{k,j} \tilde{x}_{k,j} \leq \hat{p} + u_{\max}.$$  

(43)

On the other hand, by Lemma 5 it follows that

$$\cos \frac{\phi}{2} \cdot \sum_{(k,j) \in S^*} |s_{k,j}| \leq \sum_{(k,j) \in S^*} s_{k,j} \leq C.$$  

(44)

Note that the subset $S^*$, which is an optimal solution to (1-CSP), becomes a feasible solution to RX1-CSP if the relaxed decision variables are set $x_{k,j} = \cos \frac{\phi}{2}$ for all $(k,j) \in S^*$, $x_{k,0} = 1 - \sum_{(k,j) \in S^*} x_{k,j}$ and $x_{k,j} = 0$ otherwise. This implies that

$$\text{Opt}^* \geq \sum_{(k,j) \in S^*} u_{k,j} = \cos \frac{\phi}{2} \cdot \text{Opt}.$$  

(45)

Denote by $Z^{\Delta\hat{s}}$ the utility of the output solution of 1-CSP-Greedy when applied to 1-CSP problem. To investigate the worst case approximation ratio of 1-CSP-Greedy for 1-CSP problem, consider Eqn. (13) and observe that

$$\text{Opt}^* \leq \hat{p} + u_{\max}.$$  

(46)

19
Algorithm 4 1-CSP-Greedy[$\{u_{k,j}, s_{k,j}\}_{k \in \mathcal{N}, j \in \mathcal{D}_k, C}$]

Require: Users’ utilities and demands $\{u_{k,j}, s_{k,j}\}_{k \in \mathcal{N}, j \in \mathcal{D}_k}$; capacity $C$

Ensure: $(1/2 \cos \phi, 1)$-solution $\bar{x}$ to 1-CSP

Initialization:

- Add a dummy demand with zero utility and zero demand to each set $D_k$, $k \in \mathcal{N}$
- Sort users in each set $D_k$, $k \in \mathcal{N}$ by the magnitude of their demands in increasing order such that if $j \leq j'$, then $|s_{k,j}| \leq |s_{k,j'}|$ for all $j, j' \in D_k$
- For each $k \in \mathcal{N}$ define a new set $R_k \subseteq D_k$ by successively testing the demands in $D_k$ according to Eqns. (37)-(40). Assume the ordering $|s_{k,1}| \leq |s_{k,2}| \leq \ldots \leq |s_{k,r_k}|$ in $R_k$, where $r_k = |R_k|$
- $E \leftarrow \emptyset$, $\hat{x} \leftarrow 0$, $\hat{x}_{k,0} \leftarrow 1$ for all $k \in \mathcal{N}$, $\tau \leftarrow 0$, $\tilde{x} \leftarrow \hat{x}$

1: for $k \in \mathcal{N}$, $j = 1, \ldots, r_k$ do 2: $\tilde{u}_{k,j} \leftarrow u_{k,j} - u_{k,j-1}$, $\tilde{s}_{k,j} \leftarrow s_{k,j} - s_{k,j-1}$ 3: $E \leftarrow E \cup \{(k, j)\}$ 4: end for 5: Sort items in $E$ by their efficiency $(\tilde{u}_{k,j}/|\tilde{s}_{k,j}|)$ in a non-increasing order 6: for $(k, j) \in E$ (in the sorted order) do 7: if $\tau + |\tilde{s}_{k,j}| \leq C$ then 8: $\hat{x}_{k,j} \leftarrow 1$, $\hat{x}_{k,j-1} \leftarrow 0$, $\tau \leftarrow \tau + |\tilde{s}_{k,j}|$ 9: break 10: end if 11: end for 12: Set $\tilde{x}_{k',j'} \leftarrow 1$ for $(k', j') \triangleq \arg \max_{j \in \mathcal{D}_k} \{u_{k,j}\}$, $\tilde{x}_{k',0} \leftarrow 0$ 13: Set $\bar{x} \leftarrow \arg \max_{x \in \{\tilde{x}, \hat{x}\}} u(x)$ 14: return $\bar{x}$

Evidently, $Z^{\text{ALG}} \geq \hat{p}$. This gives

$$\text{Opt}^* \leq Z^{\text{ALG}} + u_{\max}. \tag{47}$$

From the formulation of algorithm 1-CSP-Greedy, $Z^{\text{ALG}} \geq u_{\max}$, and hence by Eqns. (47) and (45) it follows that

$$Z^{\text{ALG}} \geq \frac{1}{2} \cos \phi \cdot \text{Opt}. \tag{48}$$

Finally, note that the solution $\bar{x}$ is feasible for (1-CSP) by the triangular inequality.

7. Extension to the Mixed Case

In practical applications of the complex-demand scheduling problem, we may have the situation when some of the users’ demands are elastic in the sense that they can be partially satisfied. An example is an appliance that should be either supplied with a fixed amount of power, or switched off. Formally, we may assume that each user’s demand is composed of two sets $D_k = D_k^I \cup D_k^F$, where each is a set of demands of the
form \( \{s_{k,j}(t)\}_{t \in T_j} \), as before. A feasible solution now would select, for each user \( k \), one of the demands in \( j \in D_k \) and assign either \( x_{k,j} \in \{0,1\} \) if \( j \in D^e_k \) or \( x_{k,j} \in [0,1] \) if \( j \in D^o_k \).

We show in this section that we can reduce this mixed case to the fully inelastic case. First, we note that

\[
\text{OPT} \geq \text{LB} \triangleq \max \left\{ \max_{k \in \mathcal{N}} \sum_{j \in D^e_k} u_{k,j}, \max_{k \in \mathcal{N}} \min_{t \in T_j} \frac{u_{k,j} C_t}{|s_{k,j}(t)|}, u_{k,j} \right\}. \tag{49}
\]

Let \( \mathcal{O} = \{u_{k,j}, \{s_{k,j}(t)\}_{t \in T_j}\}_{k \in \mathcal{N}, j \in D^e_k} \cup \{u_{k,j}, \{s_{k,j}(t)\}_{t \in T_j}\}_{k \in \mathcal{N}, j \in D^o_k} \), we construct a fully inelastic instance \( \mathcal{O}' = \{u_{k,j}, \{s'_{k,j}(t)\}_{t \in T_j}\}_{k \in \mathcal{N}, j \in D'_{k}} \) as follows. Let \( \epsilon \in (0,1) \) be an arbitrary constant. For each \( k \in \mathcal{N} \), we define the set \( D'_k = D^e_k \cup D'^o_k \), where \( D'^o_k \) is defined as follows. For each \( k \in \mathcal{N}, j \in D^o_k \), we introduce a number of \( n_{k,j} = \lceil \log_{1+\epsilon} \frac{n_{uk,j}}{LB} \rceil \) new demands, given by \( s'_{k,j}(t) = \frac{LB(1+\epsilon)^i}{n_{uk,j}} s_{k,j}(t) \) for \( t \in T_j \), with utility \( u_{k,j} = \frac{LB(1+\epsilon)^i}{n_{uk,j}} \).

Then we set \( D'^o_k = \{(j,i) : i = 1, \ldots, n_{k,j} \} \), where \((j,i) \in D'^o_k \) indices the demand \( s'_{k,j}(t) \) in \( \mathcal{O}' \); we denote the corresponding variable in the formulation (m-CSP) of the new instance by \( x'_{k,j} \).

Given a solution \( x \) for \( \mathcal{O}' \), we construct a solution \( \hat{x} \) for \( \mathcal{O} \) in the obvious way: if \( j \in D^e_k \), then we set \( \hat{x}_{k,j} = x_{k,j} \); otherwise, if \( x'_{k,j} = 1 \), we set \( \hat{x}_{k,j} = \frac{LB(1+\epsilon)^i}{n_{uk,j}} \).

**Lemma 7.** Let \( x \) be an \((\alpha,\beta)\)-approximate solution for \( \mathcal{O}' \). Then \( \hat{x} \) is a \(((1-\epsilon)\alpha,\beta)\)-approximate solution for \( \mathcal{O} \).

**Proof.** Let \( x^* \) be an optimal solution for \( \mathcal{O} \). We round \( x^* \) to a \((1-\epsilon,1)\)-approximate solution \( \tilde{x} \) for \( \mathcal{O}' \) as follows. If \( j \in D^e_k \), we keep \( \tilde{x}_{k,j} = x_{k,j} \in \{0,1\} \). Otherwise, \( x'_{k,j} \in [0,1] \) is positive only for at most one index \( j \in D^o_k \). In this case, we set \( \tilde{x}_{k,j} = 0 \) if \( x'_{k,j} < \frac{LB}{n_{uk,j}} \), and otherwise set \( \tilde{x}_{k,j} = \frac{LB(1+\epsilon)^i}{n_{uk,j}} \), where \( i \) is the largest integer \( i' \) such that \( \frac{LB(1+\epsilon)^i}{n_{uk,j}} \leq x'_{k,j} \). Note that \( \tilde{x} \) is feasible for \( \mathcal{O}' \) since \( \tilde{x} \geq x^* \). Furthermore, \( u(\tilde{x}) \geq (1-\epsilon)u(x^*) \), since the total utility corresponding to all the variables that are dropped to 0 is at most

\[
\sum_{k \in \mathcal{N}, j \in D^e_k} u_{k,j} \cdot \frac{\epsilon \cdot LB}{n_{uk,j}} \leq \epsilon \cdot \text{OPT} = \epsilon \cdot u(x^*),
\]

while for all other variables we have \( \tilde{x}_{k,j} \geq (1-\epsilon)x'_{k,j} \). Moreover,

\[
\sum_{k \in \mathcal{N}, j \in D'_{k}} s_{k,j}(t) \cdot \tilde{x}_{k,j} = \sum_{k \in \mathcal{N}, j \in D^e_k} s_{k,j}(t) + \sum_{k \in \mathcal{N}, j \in D^o_k} s_{k,j}(t) \frac{\epsilon \cdot LB(1+\epsilon)^i}{n_{uk,j}} \]

\[
\leq \sum_{k \in \mathcal{N}, j \in D^e_k} s_{k,j}(t)x_{k,j} + \sum_{k \in \mathcal{N}, j \in D^o_k} s_{k,j}(t)x'_{k,j} \leq \beta \cdot C_t,
\]

by the \( \beta \)-feasibility of \( x \) for \( \mathcal{O}' \). The lemma follows.
8. Conclusion

This paper extends the previous results known for the single time slot case (CKP) to a more general scheduling setting. When the number of time slots $m$ is constant, both the previously known PTAS and FPTAS are extended to handle multiple-time slots, multiple user preferences, and handle mixed elastic and inelastic demands. For polynomial $m$, a reduction is presented from CSP$[0, \frac{\pi}{2}]$ to the real-valued bag-UFP, which can be used to obtain algorithms for CSP$[0, \frac{\pi}{2}]$ based on bag-UFP algorithms that have bounded integrability gap for their LP-relaxation. We further presented a practical greedy algorithm that can be implemented efficiently in real systems. As a future work, it would be interesting to improve the second case (polynomial $m$) to a constant-factor approximation, following the recent results in [30]. Additionally, it might be of interest to consider different objective functions such as minimizing the maximum peak consumption at any time slot. Complementing this paper, extended algorithms have been developed for more sophisticated settings, such as online algorithm for CSP [31] and scheduling in electrical power networks [32, 33, 34, 35].

Proof of Lemma [9]

Lemma 5 ([9]). Given a set of 2D vectors \( \{d_i \in \mathbb{R}^2\}_{i=1}^n \)

\[
\frac{\sum_{i=1}^n |d_i|}{\sum_{i=1}^n d_i} \leq \sec \frac{\theta}{2},
\]

where \( \theta \) is the maximum angle between any pair of vectors and \( 0 \leq \theta \leq \frac{\pi}{2} \).

Proof. If \( \theta = 0 \) then the statement is trivial, therefore we assume otherwise. We prove \( \frac{\sum_{i=1}^n |d_i|^2}{\sum_{i=1}^n d_i^2} \leq \frac{2}{\cos \frac{\theta}{2}} \) by induction (notice that \( \sec \frac{\theta}{2} = \sqrt{\frac{2}{\cos \frac{\theta}{2}}} \)). First, we expand the left-hand side by

\[
\sum_{i=1}^n |d_i|^2 + 2 \sum_{1 \leq i < j \leq n} |d_i| \cdot |d_j| = \sum_{i=1}^n |d_i|^2 + 2 \sum_{1 \leq i < j \leq n} |d_i| \cdot |d_j| (\sin \theta_1 \sin \theta_j + \cos \theta_1 \cos \theta_j)
\]

\[
= \sum_{i=1}^n |d_i|^2 + 2 \sum_{1 \leq i < j \leq n} |d_i| \cdot |d_j| \cos (\theta_1 - \theta_j),
\]

(50)

where \( \theta_i \) is the angle that \( d_i \) makes with the \( x \) axis.

Consider the base case: \( n = 2 \). Eqn. (50) becomes

\[
\frac{|d_1|^2 + |d_2|^2 + 2|d_1| \cdot |d_2|}{|d_1|^2 + |d_2|^2 + 2|d_1| \cdot |d_2| \cos (\theta)} = f\left(\frac{|d_2|}{|d_1|}\right),
\]

(51)

where \( f(x) = \frac{1 + x^2 + 2x}{1 + x^2 + 2x \cos \theta} \). The first derivative is given by

\[
f'(x) = \frac{(1 + x^2 + 2x \cos \theta)(2x + 2) - (1 + x^2 + 2x)(2x + 2 \cos \theta)}{(1 + x^2 + 2x \cos \theta)^2}
\]

\( f'(x) \) is zero only when \( x = 1 \). Hence, \( f(1) \) is an extremum point. We compare \( f(1) \) with \( f(x) \) at the boundaries \( x \in \{0, \infty\} \):

\[
f(1) = \frac{2}{\cos \theta + 1} \geq f(0) = \lim_{x \to \infty} f(x) = 1
\]

Therefore, \( f(x) \) has a global maximum of \( \frac{2}{\cos \theta + 1} \).

Next, we proceed to the inductive step. We assume \( \frac{\sum_{i=1}^r |d_i|}{\sum_{i=1}^r d_i} \leq \sqrt{\frac{2}{\cos \theta + 1}} \) where \( r \in \{1, \ldots, n\} \). W.l.o.g., assume \( \theta_2 \geq \theta_3 \geq \cdots \geq \theta_n \geq \theta_1 \). Rewrite Eqn. (50) as

\[
(\sum_{i=1}^r |d_i|)^2 \sum_{i=1}^r |d_i|^2 + 2 \sum_{1 \leq i < j < r} |d_i| |d_j| \cos (\theta_i - \theta_j) + 2|d_r| \sum_{1 \leq i < r} |d_i| \cos (\theta_i - \theta_r)
\]

(52)
Let $g(\theta_r)$ be the denominator of Eqn. 52. We take the second derivative of $g(\theta_r)$:

$$g''(\theta_r) = -2|d_r| \sum_{1 \leq i < r} |d_i| \cos(\theta_i - \theta_r)$$

Notice that $\cos(\theta_i - \theta_r) \geq 0$, therefore the second derivative is always negative. This indicates that all local extrema in $[0, \theta_{r-1}]$ of $g(\theta_n)$ are local maxima. Hence, the minimum occurs at the boundaries:

$$\min_{\theta_r \in [0, \theta_{r-1}]} g(\theta_r) \in \{g(0), g(\theta_{r-1})\}$$

If $\theta_r \in \{0, \theta_r\}$, then there must exist at least a pair of vectors in $\{d_i\}_{i=1}^r$ with the same angle. Combining these two vectors into one, we can obtain an instance with $r - 1$ vectors. Hence, by the inductive hypothesis, the same bound holds up to $r$ vectors.
