We compile from literature the broadband SEDs of twelve TeV blazars observed simultaneously or quasi-simultaneously with Fermi/LAT and other instruments. Two SEDs are available for each of the objects and the state is identified as a low or high state according to its flux density at GeV/TeV band. The observed SEDs of BL Lac objects (BL Lacs) are fitted well with the synchrotron + synchrotron-self-Compton (syn+SSC) model, whereas the SEDs of the two flat spectrum radio quasars (FSRQs) need to include the contributions of external Compton scattering. In this scenario, it is found that the Doppler factor \( \delta \) of FSRQs is smaller than that of BL Lacs, but the magnetic field strength \( B \) of FSRQs is larger than that of BL Lacs. The increase of the peak frequency of the SEDs is accompanied with the increase of the flux for the individual sources, which seems opposite to the observational phenomena of the blazar sequence. We refer this phenomenon to blazar anti-sequence of spectral variability for individual TeV blazars. However, both the blazar sequence from FSRQs to BL Lacs and blazar anti-sequence of the spectral variability from low state to high state are accompanied by a increase of the break Lorentz factor of the electron’s spectrum \( \gamma_b \) and a decrease of \( B \). We propose a model in which the mass accretion rate \( \dot{M} \) is the driving force behind both the blazar sequence for ensembles of blazars and the blazar anti-sequence for individual blazars. Specifically we suggest that the differences in \( \langle \dot{M} \rangle \) of different blazars produce the observed blazar sequence, but \( \Delta \dot{M} \) in each blazar results in the observed blazar anti-sequence.

1. Introduction

Blazars, a subsample of active galactic nuclei (AGNs), are composed of BL Lac objects (BL Lacs) and flat spectrum radio quasars (FSRQs). It is well known that the observed emission from blazars is jet dominated and the observed broadband
spectral energy distributions (SEDs) are bimodal. Generally, the bump at the IR-optical-UV band is explained with the synchrotron process of relativistic electrons accelerated in the jets and the bump at the GeV-TeV gamma-ray band is due to the inverse Compton (IC) scattering of the same electron population. The seed photon fields may be from the synchrotron radiation themselves (the so-called SSC model\textsuperscript{1,2}) or from external radiation fields (EC), such as the broad line region (BLR)\textsuperscript{3}. Broadband SEDs obtained simultaneously or quasi-simultaneously are critical to investigate the radiation mechanisms and the physical properties of the emitting regions for the two kinds of blazars.

With a large sample of different types of blazars, Fossati et al. (1998) reported a spectral sequence of FSRQ–LBL–HBL\textsuperscript{4}, i.e., along with this sequence, observationally, an increase in the peak frequency of synchrotron radiation ($\nu_s$) corresponds to the decreases of bolometric luminosity and the ratio ($L_{IC}/L_{syn}$) of the luminosities for the high- and low-energy spectral components. Theoretically, an anti-correlation between the break Lorentz factor of electrons ($\gamma_b$) and the energy density of radiation regions ($U'$) in the comoving frame was found. So this blazar sequence was interpreted by Ghisellini et al. (1998) with the cooling of the external photon fields (such as the BLRs) of the blazars\textsuperscript{5}. The discoveries of ‘blue quasars’ posed a challenge to the previous interpretation for blazar sequence. To address this problem, Ghisellini & Tavecchio (2008) reported that, more physically, the sequence is due to the different black hole (BH) masses and accretion rates of the sources\textsuperscript{6}. According to this interpretation, the ‘blue quasars’ should have large BH masses and intermediate accretion rates and thus the emission region is beyond the BLR. Moreover, the red low-luminosity blazars should exist, which have small BH masses and relatively large accretion rates. More recently, Chen & Bai (2011) extended this sequence to narrow line Seyfert 1 galaxies\textsuperscript{7}, which are similar to the low-peak-frequency and low-luminosity blazars.

Observations show that the SED peak frequency of a TeV blazar increases with its flux, indicating a tendency that a brighter TeV emission corresponds to a harder spectrum for the emission at the X-ray and gamma-ray bands\textsuperscript{8,9}. This phenomenon seems to be opposite to the blazar sequence; we thus refer this phenomenon to blazar anti-sequence of spectral variability for individual TeV blazars. The spectral shift at different states of TeV emission for the individual sources may be due to the different $\gamma_b$ at different states\textsuperscript{9}. Thus, it seems that both the blazar sequence and anti-sequence are caused by the change of $\gamma_b$. However it remains unclear whether there are any connections between the two phenomena. So far, about forty AGNs have been detected at the TeV gamma-ray band. Except for two radio galaxies, all of the confirmed TeV AGNs are blazars. Moreover, most of the confirmed sources by Fermi/LAT are also blazars. The abundant observation data provide an excellent opportunity to reveal the physical connections between the blazar sequence and anti-sequence.
2. Sample Selection

In order to obtain well-sampled SEDs, only the TeV blazars, which have positive Fermi/LAT detections and two or more observed broadband SEDs, are considered. Twelve blazars are included in our sample, two FSRQs (3C 279 and PKS 1510-089) and ten BL Lacs (W Com, Mkn 421, Mkn 501, PKS 2155-304, 1ES 1101-232, BL Lacertae, 1ES 2344+514, 1ES 1959+650, PKS 2005-489, S5 0716+714). We compile their broadband SEDs that were simultaneously or quasi-simultaneously observed with Fermi/LAT and other instruments from literature. The two well-sampled SEDs for a source are identified as a low or high state according to the observed or extrapolated flux density at 1 TeV, except for PKS 1510-089. Because the SEDs of PKS 1510-089 are cut off at 1 TeV, the high and low states of this source are defined by the flux density at 10 GeV. The observation data of the broadband SEDs for 3C 279 and PKS 1510-089 are from literature\cite{10,11,12}.

3. Models and Results

The observed SEDs for those sources are double-peaked. For BL Lacs the external photon fields from their BLRs, if exist, are very weak and negligible, compared with the synchrotron radiation photon fields. Therefore, only the syn+SSC model is considered to fit the observed broadband SEDs of the ten BL Lacs. The detailed calculation process for the model and the strategy for parameter constraints can be found in Ref.\cite{9}. Following the methods described in Ref.\cite{9}, the SEDs for the ten BL Lacs are fitted well by the single-zone syn+SSC model; the fitting results and parameters can be found in Fig. 1 and table 1 of Ref.\cite{9}.

For the two FSRQs, the contributions of external field photons from their BLRs need to be considered. The total luminosities from the BLRs for the two FSRQs are taken from Ref.\cite{13} and then the BLR sizes are calculated using the BLR luminosity with formula (23) given in Ref.\cite{14}. The radiation from a BLR is assumed to be a blackbody spectrum and the corresponding energy densities seen in the comoving frame are $U'_{BLR} = 5.37 \times 10^{-3} \Gamma^2$ erg cm$^{-3}$ and $U'_{BLR} = 4.98 \times 10^{-3} \Gamma^2$ erg cm$^{-3}$ for 3C 279 and PKS 1510-089, respectively, where we take $\Gamma = \delta$. Thus, the syn+SSC+EC/BLR model is used to fit the observed SEDs of the two FSRQs and the model can explain the observed SEDs well as shown in Fig. 1.

The range of $\delta$ for these BL Lacs is from 8 to 50 and is clustered at $11 \sim 30$. On average, $\delta$ of BL Lacs is larger than that of the FSRQs, but the magnetic field strength $B$ of BL Lacs is smaller than that of the FSRQs, consistent with the results of some previous works\cite{15,16}. The values of $\gamma_b$ for these BL Lacs vary from $10^3$ to $10^6$, but the values of $B$ are clustered around 0.1 $\sim$ 0.6 G. No correlation between $\gamma_b$ and $B$ for these BL Lacs is found.
4. The Blazar Anti-Sequence and the Blazar Sequence

4.1. The Blazar Anti-Sequence

As shown in Fig. 1 and Fig. 1 in Ref. 9, there are clear spectral shifts accompanying the flux variations for these TeV blazars. The SEDs of the twelve TeV blazars in our sample are obtained in the low and high TeV states, which is defined according to the flux density at 1 TeV except for PKS 1510-089, for which the state is defined according to its flux density at 10 GeV. We compare $\nu_s$ and $\nu_c$ between the high and low states in Fig. 2(a). It is clear that the SEDs in the high states shift to a higher energy band than that in the low state.

As reported in our previous paper 9, to investigate what may be responsible for the spectral shift in the low and high states, we derive the ratios of the flux density at 1 TeV ($R_{1\text{ TeV}}$) and the physical parameters ($R_x$) in the high state to that in the low state, where $x$ stands for $L_{\text{bol}}$, $B$, $\delta$, $\gamma_b$, or $P_{\text{jet}}$. The results on the SEDs of PKS 1510-089 are not included here. The values of $\gamma_b$, $L_{\text{bol}}$, and $P_{\text{jet}}$ of the high states are systematically higher than that of the low state. A tentative correlation between $R_{\gamma_b}$ and $R_{1\text{ TeV}}$ is found with a correlation coefficient $r = 0.55$ and a chance probability $p = 0.077$ as shown in Fig. 2(b). Therefore, it is possible that the spectral shift at different states is due to the different $\gamma_b$ of these sources.

In order to compare the differences of parameters for the high and low states, we also calculate the magnetic field energy density ($U_B$), the available photon energy density ($U'_{\text{ph}}$, $U'_{\text{ph}} = U'_{\text{BLR}} + U'_{\text{syn,avail}}$ for FSRQs and $U'_{\text{ph}} = U'_{\text{syn,avail}}$ for BL Lacs) for IC process in the comoving frame, the luminosities of the synchrotron radiation ($L_{\text{syn}}$) and the IC process ($L_{\text{IC}}$, $L_{\text{IC}} = L_{\text{SSC}}$ for BL Lacs and $L_{\text{IC}} = L_{\text{SSC}} + L_{\text{EC}}$ for FSRQs) in high and low states. The ratios of those parameters for the two states ($R_{U_B}$, $R_{U'_{\text{ph}}}$, $R_{L_{\text{syn}}}$, and $R_{L_{\text{IC}}}$) as a function of the ratio of $\gamma_b$ ($R_{\gamma_b}$) are shown in Fig. 3. No correlations between the ratios of those parameters and the ratio of $\gamma_b$ are found. As presented in Fig. 3(a), for most of the sources $U_B$ becomes smaller in the high state than in the low state. However, the ratios of $U'_{\text{ph}}$, $L_{\text{syn}}$, and $L_{\text{IC}}$ are larger than unity for most of the sources as presented in Fig. 3(a), (b).

4.2. The Blazar Sequence

As described in section 1, according to the observational phenomenon of the blazar sequence, one can expect that both $L_{\text{bol}}$ and $L_{\text{IC}}/L_{\text{syn}}$ are anti-correlated with $\nu_s$, $L_{\text{bol}}$ and $L_{\text{IC}}/L_{\text{syn}}$ as a function of $\nu_s$ are shown in Fig. 4(a) and (b). A weak correlation is found for $\nu_s - L_{\text{bol}}$. The Spearman correlation analysis yields a correlation coefficient $r = -0.58$ and a chance probability $p = 0.05$ for the high state data, $r = -0.61$ and $p = 0.04$ for low state data, respectively. Excluding the two FSRQs, no correlation would be found. However, the ratio of $L_{\text{IC}}/L_{\text{syn}}$ is indeed anti-correlated with $\nu_s$, especially in their low states. The Spearman correlation analysis yields a correlation coefficient $r = -0.71$ and a chance probability $p = 0.009$ for the high state data, $r = -0.94$ and $p < 10^{-4}$ for the low state data, respectively.
Because most of the sources in our sample are BL Lacs, the external photon fields outside their jets are much weaker than the synchrotron radiation photon field and the EC process is thus not considered for these sources. As $\nu_s$ increases, the SEDs shift to the higher frequency end and the KN effect should be more significant. According to equation (20) in Ref. [17],

$$U'_\text{syn, avail} = U'_\text{syn} (\frac{3mc^2}{4\hbar \gamma_b \nu_s})^{1-\alpha_1},$$

the available photon energy density of synchrotron radiation for IC process decreases with the increase of $\gamma_b$. For $L_{\text{SSC}} \sim U'_\text{syn}$, the ratio of $L_{\text{SSC}}/L_{\text{syn}}$ would decrease as $\nu_s$ increases, since $U_B$ is almost constant and $U'_\text{syn, avail}$ decrease along with the increase of $\gamma_b$ for the BL Lacs in our sample. Therefore, the anti-correlation of $L_{\text{IC}}/L_{\text{syn}} - \nu_s$ may be also due to the KN effect, especially for BL Lacs.

Because the interpretation for blazar sequence is cooling of the external photon fields, a more “theoretical” scenario than the purely phenomenological sequence is the anti-correlation between the break Lorentz factor of electrons $\gamma_b$ and the energy density of radiation regions $U'$ in the comoving frame [15]. $\gamma_b$ as a function of $U'$ ($U' = U'_\text{syn, avail} + U'_B$ for BL Lacs, $U' = U'_\text{syn, avail} + U'_\text{BLR} + U'_B$ for FSRQs) is also shown in Fig. 4(c). Although the correlation between $\gamma_b$ and $U'$ of our sample sources has large scatters, especially for BL Lacs, comparing our results with that in Ref. [15], the two results are consistent and the BL Lacs included in our sample distribute in the left top of Fig. 4(c), where the EC process is not important. If the different $\gamma_b$ is totally due to the different external photon field, there should be a correlation between the luminosity of the BLR and the peak frequency of synchrotron emission. With a FSRQs sample [18], however, no correlation between $L_{\text{BLR}}$ and $\nu_s$ is found as shown in Fig. 5(a). Sometimes, for simplicity, the luminosity and the radius of a BLR is assumed as $L_{\text{BLR}} = 0.1L_{\text{disk}}$ and $R_{\text{BLR}} = 10^{17}L^{1/2}_{\text{disk}}$. So the comoving energy density of a BLR is given by $U'_{\text{BLR}} = 3.76 \times 10^{-2} \Gamma^2 \text{ erg cm}^{-3}$ under these assumptions [16] and is totally decided by the value of $\Gamma = \delta$. Nevertheless, no correlation between $\Gamma$ and $\gamma_b$ is found either, as presented in Fig. 5(b). $\gamma_b$ is correlated with the total energy density of the emitting regions in the comoving frame as shown in Fig. 4(c), but not correlated with the energy density of the BLR. Using the sample data in Ref. [16] and our sample data, it is found that $\gamma_b$ is correlated with the magnetic field energy density, as shown in Fig. 5(c). Some works indeed demonstrate that the magnetic field strength $B$ of FSRQs is different from and larger than that of BL Lacs [15,16], also consistent with our results. So the blazar sequence may be due to the different $\gamma_b$ and $B$ of these sources.

### 4.3. Implications for Blazar Sequence and Anti-Sequence

As shown in Fig. 1 of this paper and Fig. 1 of Ref. [9], the characteristics of spectral evolution at different states for a given source are opposite to the blazar sequence. In order to investigate the physical connections of the two phenomena, firstly, we need to define another physical parameter ($R_Y$), the ratio of physical parameters in the high state to that in the low state for the twelve sources, where $Y$ stands for...
\( \nu_s, L_{\text{bol}}, L_{\text{IC}}/L_{\text{syn}}, \gamma_b, \text{and } U' \). Comparing the spectral evolution for a given source with the blazar sequence, we find the following:

(i) According to the blazar sequence, the peak frequency of synchrotron radiation increases with decreasing bolometric luminosity. The ratio of bolometric luminosity (\( R_{L_{\text{bol}}} \)) as a function of the ratio of peak frequency (\( R_{\nu_s} \)) for the two states is presented in Fig. 6(a). It is found that for most of the sources in our sample the peak frequencies of synchrotron radiation move to the higher energy band in the high state than in the low state; at the same time the bolometric luminosities increase.

(ii) According to the blazar sequence, the peak frequency of synchrotron radiation increases with decreasing ratio of the luminosities for the IC and synchrotron components. However, for most of the sources in our sample the values of \( L_{\text{IC}}/L_{\text{syn}} \) for high state become larger than that for low state, accompanied with the increase of synchrotron radiation peak frequency as shown in Fig. 6(b).

(iii) A more “theoretical” characteristic for the blazar sequence is the anti-correlation between \( \gamma_b \) and \( U' \) in the comoving frame. However, as shown in Fig. 6(c), both \( \gamma_b \) and \( U' \) of the source in the high state become larger than that in the low state.

As described above, both the blazar sequence from FSRQs to BL Lacs and anti-sequence of the individual sources from low state to high state are accompanied by an increase of \( \gamma_b \) and a decrease of \( B \), as shown in Fig. 3(a) and Fig. 5(c). Ghisellini & Tavecchio (2010) reported that the blazar sequence is linked to the different BH masses and accretion rates of different sources.\(^{15}\) We propose here that the different states of the individual objects are also linked to the variations of the accretion rate for each source. So both the blazar sequence (change of source type) and the blazar anti-sequence of spectral variability of the individual objects (change of source state) are linked to the change of accretion rate. The flow chart illustrating how the accretion rate drives the blazar sequence and the anti-sequence is shown in Fig. 7, which is explained as follows:

- Assuming the mass accretion rate \( \dot{M} \) decreases, we can explain the blazar sequence (the left branch, \((a-d)\) in the following) from FSRQs to BL Lacs and the blazar anti-sequence (the right branch, \((e-h)\) in the following) for the individual sources from the low to high states.
- \((a)\) — Assuming equipartition between the magnetic energy and other forms of energies in the accretion disk and that the magnetic fields in the jets of blazars are carried over from the disk, then we expect \( B \) decreases. If \( \gamma_b \) is determined by radiative cooling, then we expect \( \gamma_b \) increases.
- \((b)\) — Statistically AGNs with smaller BH masses have lower \( \dot{M} \) (in physical units) and thus lower bolometric luminosity \( L_{\text{bol}} \).
- \((c)\) — The BLR exists only above a critical value of the accretion rate\(^{16}\) and its luminosity is well correlated with \( L_{\text{bol}} \), though with a delay. It is well known
that the emission lines of BL Lacs are very weak, thus the second bump of their SEDs are not contributed by IC/BLR ($L_{\text{EC}}$). Therefore, the values of $L_{\text{IC}}/L_{\text{syn}}$ for FSRQs are larger that of BL Lacs as presented in Fig. 4(b).

- (d) — From FSRQs to BL Lacs, $U'_{BLR}$ and $U_B$ (see Fig. 45(c)) decrease with the increasing $\gamma_b$, resulting in an anti-correlation between $U'$ and $\gamma_b$ shown in Fig. 4(c).

- (e) — For an individual source from the low to high state ($\dot{M}$ decreases), the electron energy $\gamma_e$ should increase with $\gamma_b$ (see Fig. 2(b) for larger $\gamma_b$ in high states) and thus the bolometric luminosity increases as shown in Fig. 6(a). This explains (i) above.

- (f) — $U_B$ decreases with $\dot{M}$ (as discussed above and see Fig. 3(a)), but $U'_{\text{syn}}$ increases with $\gamma_b$ (for increasing $L_{\text{syn}}$).

- (g) — $R_{L_{\text{IC}}/L_{\text{syn}}}$ increases for the BL Lacs in the high state as shown in Fig. 6(b), because $L_{\text{IC}}$ is “boosted” from $L_{\text{syn}}$ by $\gamma_b$. For the two FSRQs, $\delta$ is larger and $B$ is smaller in high state than that in the low state, corresponding to larger $U'_{BLR}$ and smaller $U_B$, so the ratio, $R_{L_{\text{IC}}/L_{\text{syn}}}$, is also larger than unity, as shown in Fig. 6(b). This explains (ii) above.

- (h) — Less change of $U_B$ and more increase of $U'_{\text{syn}}$ result in $R_{U'}$ larger than unity for most of the BL Lacs, as shown in Fig. 6(c). This explains (iii) above.

5. Summary

We have compiled the broadband SEDs of twelve TeV blazars that were simultaneously or quasi-simultaneously observed with Fermi/LAT and other instruments from literature. Each of those sources has two broadband SEDs available, which are identified as a high or a low state according to its flux density at GeV/TeV band. We found that the syn+SSC model can well represent the observed SEDs for BL Lacs, whereas the EC/BLR contribution needs to be considered for explaining the observed SEDs of the two FSRQs. The magnetic field strength $B$ of the two FSRQs is larger, but their Doppler factor $\delta$ is smaller than that of the ten BL Lacs. Significant spectral shift to high energies accompanying with the flux increase is observed for each individual source, which seems opposite to the observational phenomenon of the blazar sequence. We refer this phenomenon to the blazar anti-sequence. However, it is found that both the blazar sequence from FSRQs to BL Lacs and the anti-sequence of the individual sources from low to high states are accompanied by an increase of $\gamma_b$ and a decrease of $B$. We propose here that the blazar sequence and the anti-sequence of spectral variability of the individual sources are driven by decreasing accretion rate. A simple flow chart, which describes qualitatively how the accretion rate contributes to the blazar sequence and anti-sequence, is also given in this paper.
