Quantum discord expresses a fundamental non-classicality of correlations more general than quantum entanglement. We combine the no-local-broadcasting theorem, semidefinite-programming characterizations of quantum fidelity and quantum separability, and a recent breakthrough result of Fawzi and Renner about quantum Markov chains to provide a hierarchy of computationally efficient lower bounds to quantum discord. Such a hierarchy converges to the surprisal of measurement recoverability introduced by Seshadreesan and Wilde, and provides a faithful lower bound to quantum discord already at the lowest non-trivial level. Furthermore, the latter constitutes by itself a valid discord-like measure of the quantumness of correlations.

PACS numbers:

Introduction.—Correlations in quantum mechanics exhibit non-classical features that include non-locality, steering, entanglement, and quantum discord. Quantum correlations play a fundamental role in quantum information processing and quantum technologies, which go from quantum cryptography to quantum metrology. While both non-locality and steering are manifestations of entanglement, quantum discord is a more general form of quantumness of correlations that includes entanglement but goes beyond it. In particular, almost all distributed states exhibit discord. This fact calls for fully elevating the study of quantum discord to the quantitative level, since just certifying that discord is present may be considered of limited interest. While several approaches to the quantification of discord have been already proposed (see, e.g., [1, 3, 21, 22] and references therein), in this paper we significantly push forward a meaningful, reliable, and practical quantitative approach to the study of quantum discord that is based on fundamental quantum features of quantum correlations, and at the same time is computationally friendly.

Quantum discord was introduced in terms of the minimum amount of correlations, as quantified by mutual information, that is necessarily lost in a local quantum measurement of a bipartite quantum state (see below for exact definitions). It is then clear that it is relatively easy to find upper bounds to quantum discord: the loss of correlations due to any measurement provides some upper bound. Nonetheless, standard quantum discord is not easily computed even in simple cases, and general easily computable lower bounds to it are similarly not known. In this paper we provide a family of lower bounds for the standard quantum discord which can reliably be computed numerically. On the other hand, they have each physical meaning, since they are based on ‘impossibility features’ (i.e., no-go theorems) related to the local manipulation of quantum correlations. Furthermore, such lower bounds satisfy the basic requests that should be imposed on any meaningful measure of quantum correlations, hence making each quantifier in the hierarchy a valid discord-like quantifier in itself.

One ‘impossibility feature’ associated to quantum discord relates to local broadcasting [21, 22], which can be seen as a generalization of broadcasting [29], itself a generalization of cloning [30]: correlations that exhibit quantum discord cannot be freely locally redistributed or shared, and indeed, discord can be exactly interpreted as the asymptotic loss in correlations necessarily associated with such an attempt [31, 32]. A very related ‘impossibility feature’ of discord deals with the ‘local re-location’ of quantum states by classical means, that is, roughly speaking, with the transmission (equivalently, storing) of the quantum information contained in quantum subsystems via classical communication (a classical memory). Indeed, it can be checked through a powerful result by Petz [33, 34] that the ability to perfectly locally broadcast (equivalently, to perfectly store by classical means) distributed quantum states reduces to the ability to perfectly locally broadcast or classically store correlations, as measured by the quantum mutual information [27, 28, 36], a feat possible—by definition—only in absence of discord. The relation between the above two ‘impossibility features’ is due to the fact that quantum information becomes classical when broadcast to many parties [32, 37, 38].

The consideration of the general, non-perfect (for states exhibiting discord) case of the classical transmission/storing of an arbitrary quantum state has recently received renewed attention also thanks to a breakthrough result of Fawzi and Renner [40] (see also [41]) that generalizes the result by Petz. In [22], Seshadreesan and Wilde explicitly suggested to approach the study of the general quantumness of correlations, and in particular their quantification, in terms of how well distributed quantum states can be locally transmitted or stored by classical means. They introduced a discord-like quantifier, the surprisal of measurement recoverability, which, thanks to the
results of \[\text{40}\], directly translates into a lower bound to
the standard quantum discord. Unfortunately, the sur-
prisal of measurement recoverability is in general not
easily computable either. In this paper, by considering
how well a quantum state can be locally broadcast, we
generalize the surprisal of measurement recoverability in
such a way to obtain numerically computable (upper and
lower bounds to it, which provably converge to it. Thus,
we also obtain computable lower bounds to the stan-
dard quantum discord. The hierarchy of lower bounds
that we introduce exploits ideas used in the characteriza-
tion and detection of entanglement via semidefinite pro-
gramming \[\text{42}\text{,44}\]. Semidefinite programming optimization
techniques \[\text{45}\] have found many other significant
applications in quantum information (see, e.g., \[\text{46}\text{,52}\]),
and, in recent times, they have been used also in the
quantification of steering \[\text{53}\text{,54}\]. Here we extend the
use of semidefinite programming for the study of quan-
tum correlations to quantum discord.

Preliminaries—We will consider finite-dimensional
systems, so that a quantum state corresponds to a d-
dimensional positive semidefinite density matrix \(\rho\) which
lives in the space \(L(\mathcal{H})\) of linear operators on a Hilbert
space \(\mathcal{H} \simeq \mathbb{C}^d\). The von Neumann entropy associated
with \(\rho\) is given by \(S(\rho) = -\text{Tr}(\rho \log \rho)\). We will indicate
by \(\text{Tr}_X\) a trace performed over every other system ex-
cept \(X\). In the case we consider a bi-
or multi-partite system, with global state \(\rho\), we denote \(S(X)_\rho = S(\rho_X)\),
where \(L(\mathcal{H}_X) \ni \rho_X = \text{Tr}_\setminus_X(\rho)\) is the reduced state of
system \(X\). The fidelity \(F(\sigma, \rho) = \text{Tr} \sqrt{\sqrt{\rho} \sigma \sqrt{\rho}}\) is a mea-
sure of how similar two states \(\rho\) and \(\sigma\) are \[\text{55}\]. It holds
\(0 \leq F(\sigma, \rho) \leq 1\), with \(F(\sigma, \rho) = 1\) if and only if \(\rho = \sigma\).
We will need the fact that the fidelity can be seen as the
to the semidefinite programming (SDP) op-
imization problem \[\text{52}\text{,55}\]

\[
\begin{align*}
\text{maximize} & \quad \frac{1}{2}(\text{Tr}(X) + \text{Tr}(X^\dagger)) \\
\text{subject to} & \quad \left( \frac{\rho}{X} X^\dagger \sigma \right) \succeq 0.
\end{align*}
\]

Another measure of similarity of states is the trace dis-
cance \(\Delta(\sigma, \rho) = \frac{1}{2}\|\sigma - \rho\|_1\) where \(\|\xi\|_1 = \text{Tr}(\sqrt{\xi^2})\)
is the trace norm \[\text{65}\]. It holds \(0 \leq \Delta(\sigma, \rho) \leq 1\), and
\(1 - F(\sigma, \rho) \leq \Delta(\sigma, \rho) \leq \sqrt{1 - F^2(\sigma, \rho)} \[\text{55}\]
Transformations of physical systems are described by completely
positive and trace-preserving linear maps, also called chan-
nels, from \(L(\mathcal{H}_{\text{in}})\) to \(L(\mathcal{H}_{\text{out}})\), where \(\mathcal{H}_{\text{in}}\) and \(\mathcal{H}_{\text{out}}\) are the input and output spaces, respectively \[\text{3}\].

Separability and symmetric extensions.—A bipartite
state \(\rho_{AB}\) is separable (or unentangled) if it admits the
decomposition \(\rho_{AB}^{\text{sep}} = \sum_k p_k |\alpha_k\rangle_\text{A} \otimes |\beta_k\rangle_\text{B}\) for \(\{p_k\}\) a probability distribution, and \(|\alpha_k\rangle_\text{A}\) and \(|\beta_k\rangle_\text{B}\) (not
necessarily orthogonal) vector states for \(A\) and \(B\), re-
spectively. A bipartite state that is not separable is en-
tangled \[\text{58}\].

Consider systems \(B_1 \simeq B_2 \simeq B\). A state \(\rho_{AB_1B_2}\) such that \(\rho_{AB_1} = \rho_{AB_2} = \rho_{AB}\), and such that
\(\rho_{AB_1B_2} = V_{B_1B_2} \rho_{AB_1B_2} V_{B_1B_2}^\dagger\) with \(V_{B_1B_2}\) the swap oper-
ator, \(V_{B_1B_2}|\beta_1\rangle_\text{B}_1 |\beta_2\rangle_\text{B}_2 = |\beta_2\rangle_\text{B}_1 |\beta_1\rangle_\text{B}_2\) is called a (two-
) symmetric extension (on \(B\)) of \(\rho_{AB}\). If the stronger con-
dition \(\rho_{AB_1B_2} = \Pi_{B_1B_2} \rho_{AB_1B_2} \Pi_{B_1B_2}\) holds, with \(\Pi_{B_1B_2}\) the projector onto the symmetric subspace of \(B_1B_2\), we call \(\rho_{AB_1B_2}\) a (two-) Bose-symmetric extension (on \(B\)). The concept can be generalized to \(k\) extensions. Let \(B^k = B_1B_2 \ldots B_k\). We say that \(\rho_{AB^k}\) is a \(k\)-symmetric extension of \(\rho_{AB}\) (on \(B\)) if: (i) \(\rho_{AB^k} = \text{Tr}_{AB^k} (\rho_{AB^k}) = \rho_{AB}\),
for all \(i = 1, \ldots, k\); (ii) \(\rho_{AB_1B_2} = V \rho_{AB} V^\dagger\) for any unitary
\(V\) that permutes the \(B^k\) systems. Note that, because of
the symmetry (ii), in (i) it is enough to consider the trace
over all systems \(B_i\) except an arbitrary one, e.g., \(B_1\). If the stronger condition (ii') \(\rho_{AB^k} = \Pi_{B_1B_2} \rho_{AB} \Pi_{B_1B_2}\) holds, with \(\Pi_{B_1B_2}\) the projector onto the fully symmetric subspace \(B^k_1\) of \(B^k\), holds, we say that \(\rho_{AB^k}\) is a \(k\)-Bose-symmetric extension of \(\rho_{AB}\) (on \(B\)). Only separable states admit
\(k\)-symmetric extensions for all \(k \geq 3\) \[\text{59}\text{,60}\].

No local broadcasting.—The no-local-broadcasting the-
orem \[\text{27}\text{,28}\] states that there exists a broadcasting
channel \(\Lambda_{B_1B_2} \rightarrow B_1B_2\) such that
\(\text{Tr}_{B_1B_2} (\Lambda_{B_1B_2} (\rho_{AB})^\dagger) = \text{Tr}_{B_1B_2} (\Lambda_{B_1B_2} \rho_{AB})\),
which outputs is symmetric among the outputs; (ii) an arbitrary number
\(k\) of extensions can be obtained, simply by \(|b\rangle \mapsto |b\rangle \otimes k\),
for \(b\) as in \(\text{2}\), i.e., with output into the fully symmetric
subspace \(B^k_1\), so that the broadcasting channel has
actually Bose-symmetric output (see Fig. \(\text{1}\)).

Consider then Bose-symmetric broadcast maps
\(\Lambda_{B_1B_2} \rightarrow B^k_1\) with output in the fully symmetric subspace \(B^k_1\),
and the induced maps \(\Lambda_{B_1B_2}^{\text{Sym}}(k) = \text{Tr}_{B_1} o \Lambda_{B_1B_2} \rightarrow B^k_1\),
where \(o\) denotes composition. We say that any map \(\Lambda_{B_1B_2}^{\text{Sym}}(k)\)
that admits such a representation is \(k\)-Bose-symmetric extendible. The no-local-broadcasting theorem can then be re-
cast as the fact that, for any \(\rho_{AB}\) that is not quantum-classical,
\(F(\rho_{AB}, \Lambda_{B_1B_2}^{\text{Sym}}(k) [\rho_{AB}]) < 1\) for any
\(k \geq 2\) and any \(k\)-Bose-symmetric extendible \(\Lambda_{B_1B_2}^{\text{Sym}}(k)\).

We now recall that every \(k\)-Bose-symmetric extendible
channel is close to an entanglement-breaking (EB)—also
called measure-and-prepare—map \[\text{61}\]

\[
\Lambda_{B_1B_2}^{\text{EB}} [\rho_{AB}] = \sum_y \text{Tr}(M^y_B |\beta_y\rangle \langle \beta_y|_B),
\]

where \(\{M^y_B\}\) is a positive-operator-valued measure
ensures that there exist a recovery channel \( \mathcal{R}_{C \to BC} \) such that \( \rho_{ABC} \), there always exists a recovery channel \( \mathcal{R}_{C \to BC} \) such that \( \rho_{ABC} \) (see also [11])

\[
F(\mathcal{R}_{C \to BC}[\rho_{AC}], \rho_{ABC}) \geq 2^{-\frac{1}{2}I(AB;C)_{\rho}},
\]

that is, roughly speaking, the smaller the decrease of correlations between \( A \) and \( BC \) due to the loss of \( B \), the better the original \( ABC \) state can be recovered from operating just on \( C \) alone.

Consider measurement maps \( \mathcal{M}_{B \to Y}[\cdot] = \sum_y \operatorname{Tr}(M_B^y) |y\rangle\langle y|_Y \), where \( \{M_B^y\} \) is a POVM, and the \( |y\rangle \)'s are orthogonal vector states. The discord of \( \rho \) between \( A \) and \( B \) with measurement on \( B \) can be defined as \(22,26\)

\[
D(A : B)_\rho = \min_{\mathcal{M}_{B \to Y}} (I(A : B)_{\rho_{AB}} - I(A : Y)_{\mathcal{M}_{B \to Y}[\rho_{AB}]}) = \min_{\mathcal{M}_{B \to Y}} (I(A : Y|E)_{\rho_{AYE}} - I(A : Y)_{\rho_{AY}}) = \min_{\mathcal{M}_{B \to Y}} I(A : Y|E)_{\rho_{AYE}},
\]

where in the second and third lines the minimization is over all isometries \( V_{B \to YE} \) that realize measurement maps \( \mathcal{M}_{B \to Y} \) with \( E \) considered as the environment of the dilation \(5,22\). That is, \( E \) is the system that is traced out, or lost, in \( \mathcal{M}_{B \to Y}[\cdot] = \operatorname{Tr}_{\mathcal{B}(B)Y}(V_{B \to YE} \cdot V_{B \to YE}^\dagger) \), and \( \rho_{AYE} = V_{B \to YE} \rho_{AB} V_{B \to YE}^\dagger \). Notice that \( I(A : B)_{\rho_{AB}} = I(A : Y|E)_{\rho_{AYE}} \). It can be proven \(28,32\) that the only states with vanishing discord are quantum-classical states of the form \(\rho_{ABC} = \mathcal{R}_{C \to BC} \rho_{AC} \).

In the case of a (local) measurement, the recovery map (for our intentions, directly to \( B \), rather than \( Y \)) can be assumed to be of the form \(22\) \( \mathcal{R}_Y \to B[\cdot] = \sum_k \operatorname{Tr}(|y\rangle\langle y|_Y \cdot \sigma_B^k) \), with \( \sigma_B^k \) states, so that the combination of measurement and recovery, \( \mathcal{R}_Y \to B \circ \mathcal{M}_{B \to Y} \), is an entanglement-breaking map \(33,61\). Then, combining \(4\) and \(7\), one has \(22\)

\[
\mathop{\sup}_{\lambda^{EB} \in \mathcal{LEB}} F(\lambda^{EB}_{B}[\rho_{AB}], \rho_{AB}) \geq 2^{-\frac{1}{2} D(A : B)}.
\]

Introducing the surprisal of measurement recoverability \(22\) \( D_F(A : B) := -\log \mathop{\sup}_{\lambda^{EB} \in \mathcal{LEB}} F^2(\lambda^{EB}_{B}[\rho_{AB}], \rho_{AB}) \), one can cast \(8\) as \( D_F(A : B) \leq D(A : B) \). The surprisal of measurement recoverability quantifies the necessary disturbance introduced by manipulating locally (on \( B \)) the state \( \rho_{AB} \), through measurement and preparation. Notice that this can be generalized to any class of maps that correspond to a non-trivial (local) manipulation (see \(21\)), i.e., one can consider \( D_F(A : B) := -\log \mathop{\sup}_{\lambda^{LE} \in \mathcal{LE}} F^2(\lambda^{LE}[\rho_{AB}], \rho_{AB}) \) for \( \mathcal{L} \) some class of channels. With this notation, we can write \( D_F(A : B) = D_{F,\mathcal{LE}}(A : B) \), where, we recall, \( \mathcal{LE} \) indicates the set of entanglement-breaking channels. Notice that if \( \mathcal{LE} \subseteq \mathcal{L} \), it necessarily holds

\[
D_{F,\mathcal{L}}(A : B) \leq D_{F,\mathcal{LEB}}(A : B) \leq D(A : B). \tag{9}
\]

(POVM) and \( |\beta_y\rangle_B^S \) are normalized vector states, not necessarily orthogonal. Entanglement-breaking maps have the defining property that, for any given \( \rho_{AB} \), \((\text{id}_A \otimes \Lambda^{EB}_B)[\rho_{AB}]\) is separable. More precisely, one can prove that for any \( k \)-Bose-symmetric extendible \( \Lambda^{Sym,(k)}_B \) there is an entanglement breaking map \( \Lambda^{EB}_B \) close to it in the so-called diamond-norm distance; more precisely \(39\):

\[
\mathop{\sup}_{\rho_{AB}} \Delta \left( \Lambda^{Sym,(k)}_B[\rho_{AB}], \Lambda^{EB}_B[\rho_{AB}] \right) \leq \frac{|B|}{k}, \tag{4}
\]

where \(|B|\) indicates the dimension of system \( B \), i.e., of \( \mathcal{H}_B \). Furthermore, it is clear that any entanglement-breaking map is \( k \)-Bose-symmetric extendible, since for any entanglement-breaking map \( \Lambda^{EB}_B[\cdot] \) we can consider \( \Lambda^{Sym,(k)}_B[\cdot] = \sum_y \operatorname{Tr}(M_B^y) |\beta_y\rangle_B^k \}^{\otimes k} \). Denote by \( \mathcal{L}^{Sym,(k)} \) the class of channels with a \( k \)-Bose-symmetric extension, and by \( \mathcal{L}^{EB} := \{ \lambda^{EB} \} \) the class of entanglement-breaking channels \( \mathcal{L}^{EB} \) \(61\). We can then write \( \mathcal{L}^{EB} \subseteq \mathcal{L}^{Sym,(k)} \) and \( \mathcal{L}^{Sym,(k)} \to \mathcal{L}^{EB} \) for \( k \to \infty \).

**Mutual information, recoverability, and discord**—The mutual information between \( A \) and \( B \) is defined as \( I(A : B)_\rho = S(A)_\rho + S(B)_\rho - S(AB)_\rho \), and it is a fundamental measure of the total correlations present between \( A \) and \( B \) \(5,62,63\). The conditional mutual information can be defined as \(3,5\) \( I(A : B|C)_\rho = I(A : BC)_\rho - I(A : C)_\rho \), i.e., it is equivalent to the decrease of correlations between \( A \) and \( BC \) due to the loss of system \( B \). The celebrated strong subadditivity of the von Neumann entropy \(64\) is equivalent to

\[
I(A : B|C)_\rho \geq 0. \tag{5}
\]

When \(5\) is satisfied with equality, \( \rho_{ABC} \) is said to form a Markov chain: indeed, a strong result by Petz \(35,37\) ensures that there exist a recovery channel \( \mathcal{R}_{C \to BC} \) such that \( \rho_{ABC} = \mathcal{R}_{C \to BC}[\rho_{AC}] \). Fawzi and Renner recently generalized this by proving that, for any tripartite state

\[
\rho_{ABC}, \text{ there always exists a recovery channel } \mathcal{R}_{C \to BC} \text{ such that } 40, \text{ (see also 41)}
\]

FIG. 1: Symmetric local broadcasting (colour online). A local Bose-k-symmetric broadcasting channel \( \Lambda_{B \to B^+_k} \) maps \( B \) to the fully symmetric subspace of \( B^k = B_1B_2 \ldots B_k \). The degree to which \( \rho_{AB^1} = \operatorname{Tr}_{AB^1}[\Lambda_{B \to B^+_k}[\rho_{AB}]] \) can approximate the initial state \( \rho_{AB} \) depends on the classicality of correlations between \( A \) and \( B \).
In particular, we will consider $\mathcal{L} = \mathcal{L}^{\text{Sym}(k)}$. Notice that, in the other direction, Eq. (10) implies (see Appendix) $\sup_{\Lambda \in \mathcal{L}^{\text{Sym}(k)}} F(\rho_{AB}, \Lambda_B^{\text{Sym}(k)}[\rho_{AB}]) \geq \sup_{\Lambda \in \mathcal{L}^{\text{Sym}(k)}} F(\rho_{AB}, \Lambda_B^{\text{Sym}(k)}[\rho_{AB}]) - \sqrt{2|B|}/k$, so $D_{F,\mathcal{L}^{\text{Sym}(k)}}(A:B) \rightarrow D_{F,\mathcal{L}^{\text{Sym}}}(A:B)$ for $k \rightarrow \infty$.

Choi-Jamiolkowski isomorphism and $k$-extendible maps.—The Choi-Jamiolkowski isomorphism [65, 66] is a one-to-one correspondence between linear maps $\Lambda_{X \rightarrow Y}$ from $L(\mathcal{H}_X)$ to $L(\mathcal{H}_Y)$ and linear operators $W_{XY}$ in $L(\mathcal{H}_X \otimes \mathcal{H}_Y)$. It reads

$$J(\Lambda)_{XY} = (\text{id}_X \otimes \Lambda_{X' \rightarrow Y})(\tilde{\psi}^+_{XX'}),$$

with inverse

$$(J^{-1}(W_{XY}))_{X' \rightarrow Y}[\rho_X] = \text{Tr}_X(W_{XY}^\Gamma \rho_X).$$

Here $\tilde{\psi}^+_{XX'} = |\tilde{\psi}^+\rangle\langle \tilde{\psi}^+|_{XX'}$, with the unnormalized maximally entangled state $|\tilde{\psi}^+\rangle_{XX'} = \sum_x |x\rangle_X |x\rangle_{X'}$, for $\{|x\rangle\}$ an orthonormal basis of $\mathcal{H}_X$, and $\Gamma_X$ indicates partial transposition on $X$. The operator $J(\Lambda)$ encodes all the information about the map $\Lambda$. In particular, the linear map $(J^{-1}(W_{XY}))_{X' \rightarrow Y}$ defined via (11) is a valid quantum channel from $X$ to $Y$ if and only if $W_{XY}$ is positive semidefinite and $W_X = \text{Tr}_Y(W_{XY}) = \mathbb{1}_X$. Also, $(J^{-1}(W_{XY}))_{X' \rightarrow Y}$ is an entanglement breaking channel if and only if $W_{XY}$ satisfies the additional condition of being proportional to a separable state. Finally, it is easily checked that $J^{-1}(W_{XY})_{X' \rightarrow Y}$ is a $k$-Bose-symmetric extendible channel if and only if, besides satisfying the conditions to be isomorphic to a channel, $W_{XY}$ admits $k$-Bose-symmetric extensions on $Y$.

A faithful SDP lower bound to quantum discord—The major obstacle in the computation of the surprisal of measurement recoverability is the fact that it requires an optimization over entanglement breaking channels, i.e., via the Choi-Jamiolkowski isomorphism, over separable states, which cannot be easily parametrized.

In our case, relaxing the problem, we choose to maximize the fidelity between $\rho = \rho_{AB}$ and $\sigma = (\text{id}_A \otimes \Lambda_B^{\text{Sym}(k)})[\rho_{AB}]$, optimizing over $\Lambda_B^{\text{Sym}(k)} \in L^{\text{Sym}(k)}$. The Choi-Jamiolkowski isomorphism allows us to write this as an optimization over positive semidefinite operators $W_{BB'}$ that satisfy $W_B = \mathbb{1}_B$ and admit $k$-Bose-symmetric extensions. Hence we can write this as an optimization over extended operators $W_{BB'}$ isomorphic to $k$-Bose-symmetric broadcasting channels. Putting everything together, we find that $\sup_{\Lambda \in \mathcal{L}^{\text{Sym}(k)}} F(\rho_{AB}, \Lambda_B[\rho_{AB}])$, from which $D_{F,\mathcal{L}^{\text{Sym}(k)}}(A:B)$ can be derived, corresponds to the solution of the following SDP optimization problem:

maximize \[ \frac{1}{2} (\text{Tr}(X) + \text{Tr}(X^\dagger)) \] (12a)
subject to \[ \begin{pmatrix} \rho_{AB} & X \\ X^\dagger & \text{Tr}_A(B_{BB'}W_{BB'}) \end{pmatrix} \succeq 0 \] (12b)
\[ W_{BB'} \geq 0 \] (12c)
\[ W_B = \mathbb{1}_B \] (12d)
\[ W_{BB'} = \Pi_{B'}^\dagger W_{BB'} \Pi_{B'} \] (12e)

We already argued that $D_{F,\mathcal{L}^{\text{Sym}(k)}}(A:B)$ converges to $D_{F,\mathcal{L}^{\text{Sym}}}(A:B)$. To see that it does so monotonically, i.e., that $D_{F,\mathcal{L}^{\text{Sym}(k+1)}}(A:B) \geq D_{F,\mathcal{L}^{\text{Sym}(k)}}(A:B)$, it is enough to notice that, if $W_{BB'+1}$ is Bose-symmetric on $B^{k+1}$, then $\text{Tr}_{B^{k+1}}(W_{BB'+1})$ is Bose-symmetric on $B^k$. We also remark again that $D_{F,\mathcal{L}^{\text{Sym}}}(A:B)$ is already a faithful quantifier of discord, in the sense that, thanks to the no-local-broadcasting theorem, we know it is strictly positive for any state that is not classical on $B$. Finally, thanks to the properties of the fidelity $F$, in particular its monotonicity under quantum operations, i.e., $F(\Lambda[\sigma], \Lambda[\rho]) \geq F(\sigma, \rho)$ [25], it is immediate to check that each $D_{F,\mathcal{L}^{\text{Sym}(k)}}(A:B)$ is invariant under local unitaries on $B$, and monotonically decreasing under general local operations on $A$ [22]. Thus, each $D_{F,\mathcal{L}^{\text{Sym}(k)}}(A:B)$, in particular in the case $k = 2$, constitutes in itself a well-behaved measure of the general quantumness of correlations [25, 26].

Notice that, if the goal is that of lower-bounding the surprisal of measurement recoverability—and in turn...
standard discord—rather than just considering a class of physical channels like Bose-symmetric extendible ones, we can impose additional ‘unphysical’ properties that nonetheless make the considered class more closely approximate the class of entanglement-breaking channels. Correspondingly, the SDP optimization \[ \text{Tr} \] can be modified to include additional constraints, in particular asking for \( W_{\text{BB}} \) to be positive under partial transposition (PPT) in any bipartite cut. In particular, simply by asking that it is PPT with respect to the \( B : B^\text{op} \) partition, e.g., by adding to \( \text{Tr} \) the condition \( W_{\text{BB}}^\text{op} \geq 0 \), we make the corresponding k-Bose-extendible channel PPT binding 69, i.e., such that the state \((\id_A \otimes \Lambda_B)[\sigma_{AB}]\) is PPT for all \( \sigma_{AB} \). This is a non-trivial constraint also for the case \( k = 1 \), and, in the case \( |B| = 2 \), enough to make the channel entanglement breaking \[ \text{Tr} \] so that in this case the solution to the SDP provides exactly the surprisal of measurement recoverability. We implemented \[ \text{Tr} \] in MATLAB 71, making use of CVX 72, 73 and other tools publicly available 74, 75. An example of the results is presented in Figure 2.

**Discord, entanglement, and symmetric extensions.**—Our approach, based on an SDP hierarchy dealing with symmetric extensions, is inspired by and very similar to the one used to verify entanglement 42, 43 (see also 46) for applications to the extendability of channels. In turn, the fact that fidelity can be expressed as an SDP program, which we exploited here, could also be adopted for the study and quantification of entanglement, providing a hierarchy of SDP programs that allows to calculate the largest fidelity of the given state \( \rho_{AB} \) with any state \( \sigma_{AB}^{\text{Sym}(k)} \) admitting a (Bose-)\( k \)-symmetric extension on \( B \), and converging to the fidelity of separability 76. Our approach points to a illuminating conceptual relation between entanglement and discord, in terms of symmetric extensions and how they are generated: entanglement limits how well a state can be approximated by a state admitting a \( k \)-symmetric extension, and only separable states can be perfectly approximated for all \( k \geq 2 \); on the other hand, discord limits how well a state can be locally transformed into a (Bose-)\( k \)-symmetric extension of itself, with only discord-free states that can be perfectly locally broadcast, for any \( k \geq 2 \). Remarkably, while entanglement can be exactly characterized only in the limit \( k \to \infty \), discord can be pinned down already by considering the case \( k = 2 \)—this is the content of the no-local-broadcasting theorem. This explains why, while entanglement verification is hard 77, 78, our hierarchy provides a faithful, reliable, and efficiently computable lower bound to discord already at the lowest level.

**Conclusions.**—We have introduced a hierarchy of discord-like quantifiers. They are defined in terms of how well a given quantum state \( \rho_{AB} \) can be locally broadcast. More precisely, in the lowest non-trivial level of the hierarchy, our quantifier answers the following question: Consider any mapping from \( B \) to the symmetric subspace of two copies \( B_1B_2 \) of \( B \); how well can the resulting \( \rho_{AB_1} \) (equivalently, \( \rho_{AB_2} \)) approximate the original \( \rho_{AB} \)? In the limit where we consider infinite copies of \( B \), instead of just two, the question becomes that of how well the information about \( B \) contained in \( \rho_{AB} \) can be transmitted (equivalently, stored) in the form of classical information, through a measure, transmit (store), and re-prepare process. Our hierarchy is faithful at all non-trivial levels, i.e., the quantifiers are non-vanishing for states that are not classical on \( B \). Each element in the hierarchy corresponds to an SDP optimization problem; hence, it can be reliably and efficiently (in the dimensions of the systems) computed numerically 42, 43. Furthermore, while each element has a clear physical meaning in itself and satisfies the basic properties to be expected for a meaningful quantifier of the quantumness, it also constitutes a lower bound to the standard quantum discord. Remarkably, in the case in which we are interested in the discord features of a qubit-qudit system, with measurement on the qudit, a tailored SDP program can provide exactly, i.e., up to numerical error, the surprisal of measurement recoverability defined by Seshadreesan and Wilde 22, and thus the best possible lower bound to standard quantum discord based on the breakthrough result about quantum Markov chains of Fawzi and Renner 41.

The first inequality is just the triangle inequality for the absolute value. The second inequality is due to the fact that the fidelity between two states is the maximum overlap of any two purifications of the states \([5, 80]\).

The last inequality is due to the standard relation \(1 - F(\tau, \rho) \leq \Delta(\tau, \rho) \leq 1 - \Lambda(\rho, \sigma)\).

**Theorem 1.** It holds

\[
\sup_{\Lambda^{EB}} F(\rho_{AB}, \Lambda^{EB}_{\Lambda}[\rho_{AB}]) \\
\geq \sup_{\Lambda^{Sym_{+}(k)}} F(\rho_{AB}, \Lambda^{\text{Sym}_{+}(k)}_{\Lambda}[\rho_{AB}]) - \sqrt{\frac{2|B|}{k}}.
\]

**Proof.** Eq. (11) implies that, for any \(\Lambda^{\text{Sym}_{+}(k)}\), there is \(\Lambda^{EB}\) such that, for any \(\rho_{AB}\)

\[
\Delta\left(\Lambda^{\text{Sym}_{+}(k)}_{\Lambda}[\rho_{AB}], \Lambda^{EB}_{\Lambda}[\rho_{AB}]\right) \leq \frac{|B|}{k}.
\]

Thus, using Lemma 1 we obtain

\[
F(\rho_{AB}, \Lambda^{EB}_{\Lambda}[\rho_{AB}]) \\
\geq F(\rho_{AB}, \Lambda^{\text{Sym}_{+}(k)}_{\Lambda}[\rho_{AB}]) \\
- \sqrt{\frac{2|B|}{k}}.
\]

Since this is valid for any \(\Lambda^{\text{Sym}_{+}(k)}\), we can take the supremum on both sides over channels in the respective classes.
