Abstract. We discuss the transition strength between the disordered ground state and the basic low-lying triplet excitation for interacting dimer materials by presenting theoretical calculations and series expansions as well as inelastic neutron scattering results for the material KCuCl₃. We describe in detail the features resulting from the presence of two differently oriented dimers per unit cell and show how energies and spectral weights of the resulting two modes are related to each other. We present results from the perturbation expansion in the interdimer interaction strength and thus demonstrate that the wave vector dependence of the simple dimer approximation is modified in higher orders. Explicit results are given in 10th order for dimers coupled in 1D, and in 2nd order for dimers coupled in 3D with application to KCuCl₃ and TlCuCl₃.

1. Introduction

Low-dimensional quantum antiferromagnets have received much interest in recent years since they serve as model substances allowing to investigate in detail the effects of quantum fluctuations and to test theoretical models. One important class of materials in this context consists of an assembly of dimers (two strongly coupled spins 1/2) which interact sufficiently weakly to guarantee that the dimer gap does not close. These materials are characterized by a disordered singlet ground state and a finite spin gap to triplet excited states. Prominent examples in this class are KCuCl$_3$ and TlCuCl$_3$ which have been investigated in detail in the last years by static and dynamic methods as well as theoretically [1]. The most detailed experimental information is obtained from inelastic neutron scattering (INS) experiments, which directly explore the basic singlet-triplet transition in all of reciprocal space [2, 3].

The energy of the singlet-triplet transition along the principal axis in reciprocal space as measured in these experiments is well described by the model of interacting dimers; to lowest order this is formulated as effective dimer model [4, 5], and it has been refined by perturbative cluster expansions up to 6$^{th}$ order [3]. Here we supplement this analysis by discussing the dynamical structure factor.

The dynamical structure factor for spins localized on a Bravais lattice is defined as

$$S^{\alpha \beta}(q, \omega) = \int_{-\infty}^{\infty} dt \ e^{-i\omega t} \langle S^\alpha(q,t)S^\beta(-q,0) \rangle$$  

(1)

where

$$S^\alpha(q,t) = \sum_R e^{-iqR} S^\alpha(R,t)$$  

(2)

is the Fourier transformation of the spin operators at lattice sites $R$. The superscripts $\alpha, \beta$ denote the spin components and the brakets $\langle \cdots \rangle$ thermal expectation values (which for $T = 0$ reduce to groundstate expectation values $\langle 0 | \cdots | 0 \rangle$). Apart from known prefactors, Eq. (1) reflects the spectral weight from the magnetic neutron scattering cross section [6].

If we consider transitions from the ground state $|0\rangle$ to some well-defined eigenstate $|n\rangle$ with energy $\omega_n(q)$, we obtain $\delta$-peaked contributions to the dynamical structure factor

$$S^{\alpha \beta}(q, \omega) = \sum_n \langle 0 | S^\alpha(q) | n \rangle \langle n | S^\beta(-q) | 0 \rangle \delta(\omega - \omega_n(q))$$  

(3)

$$= \sum_n I^\alpha \beta_n(q) \delta(\omega - \omega_n(q)).$$  

(4)

In interacting dimer materials, INS probes directly the transition from the (singlet) ground state $|0\rangle$ to the lowest (triplet) excitation $|t\rangle$ and we will reduce our discussion to this contribution to the dynamical structure factor. Owing to the rotational symmetry of the underlying Heisenberg model it is sufficient to calculate $I^{zz}_n(q)$ only and we use the shorthand $I_{sm}(q) := I^{zz}_n(q)$ to denote the lowest triplet (single magnon) contribution to the spectral weight.
The INS investigation of the materials KCuCl$_3$ and TlCuCl$_3$ at finite magnetic fields provides direct verification of this point as reported in [7].

The discussion of our results is organized as follows. In section II we will give theoretical results for a 1D array of interacting dimers. This model was treated before [8], it is, however, instructive to demonstrate for the simple 1D case, that existing standard expansions are modified by additional terms which emerge starting in second order. In addition we present the quantitative changes for the transition strength comparing first order to $10^{th}$ order results to show the effect of high order calculations. In section III we discuss interacting dimers in a 3D network by presenting in parallel neutron scattering results for the material KCuCl$_3$ and series expansions to $2^{nd}$ order. The same type of additional terms as in 1D is obtained in this calculation and corrects the results for the dynamical structure factor as obtained in the random phase approximation (RPA) before, see Ref. [9]. These RPA results are found to be correct only to first order. Section IV gives our conclusions.

2. Alternating chain

First we consider the one dimensional (1D) alternating $S = 1/2$ spin chain with isotropic nearest-neigbour interactions. The hamiltonian of this model is of the following form

$$H = J \sum_{n=1}^{N} (S_1(n) \cdot S_2(n) + \lambda S_2(n) \cdot S_1(n+1)), \quad J > 0. \quad (5)$$

Here, the alternating chain is described as a system with $N$ unit cells with two spins each and periodic boundary conditions are used. There are two exchange constants, $J$ and $\lambda J$, for $\lambda = 0$ the ground state of the system consists of singlets on the intracell bonds $(n, 1) - (n, 2)$. These local singlets can be excited to triplets which remain gapped excitations when switching on $\lambda$, $0 < \lambda < 1$. In the limit $\lambda = 1$ we arrive at the well known Heisenberg antiferromagnet (HAFM) with pairs of $S = 1/2$ spinons as lowest gapless excitations. Other related models are described in Ref. [10].

The triplet excitation energies $\omega(q)$ have been obtained by perturbation expansion in $\lambda$ up to $9^{th}$ order in Ref. [8] and to $10^{th}$ order in Ref. [5] using the cluster expansion approach.

2.1. The dynamical structure factor

Turning to the calculation of the structure factor for a system with hamiltonian (5), we note (see Eqs. (1,2)) that for this calculation we have to specify the positions of the spins, $R$, in space (whereas the eigenvalues depend solely on the exchange constants). In slight generalization of a strictly linear geometry we allow for our calculation the separation $d$ of two spins in one unit cell to be different in magnitude and direction from the separation $a$ of two adjacent spins in different unit cells (note that $a$ defines the overall chain direction). The resulting geometry is shown in Figure A1 and makes clear the relation to the real 3D systems to be dealt with in the next section: the
1D chain defined in Eq. (5) can alternatively be looked at as a ladder with rung and diagonal interactions only. For the chain geometry shown in Figure A1 the spectral intensity up to first order in $\lambda$ is obtained as follows

$$I_{sm}(q) = \sin^2 \frac{qd}{2}(1 + \frac{1}{2}\lambda \cos(qa)) + O(\lambda^2). \tag{6}$$

Here, $q$ is the wave vector, $d$ and $a$ the separation of the spin sites within and between the dimers, respectively. We note that the term $\propto \sin^2(qd/2)$ is typical for systems consisting of isolated dimers, it is known as the dimer structure factor [11]. The first order correction in $\lambda$ adds an additional modulation to the intensity, which depends on the ratio $\sigma = \|d\|/\|a\|$.

Using the cluster expansion method (see Appendix A) we have systematically calculated the series in $\lambda$ for the intensity up to the tenth order. This requires linked clusters consisting of maximum 10 bonds. The resulting series can be split into three different terms:

$$I_{sm}(q) = B_c(q, \lambda) + B_s(q, \lambda) + \Lambda(q, \lambda). \tag{7}$$

To illustrate the result we give the series up to fourth order‡:

$$B_c(q, \lambda) = \sin^2 \frac{qd}{2} \sum_{j=0}^4 \mu_j \cos(jqa),$$

$$B_s(q, \lambda) = \sin qd \sum_{j=0}^4 \nu_j \sin(jqa) \tag{8}$$

where

$$\mu_0 = 1 - \frac{5}{16} \lambda^2 - \frac{3}{32} \lambda^3 + \frac{25}{1536} \lambda^4, \quad \nu_0 = 0,$$

$$\mu_1 = \frac{1}{2} \lambda - \frac{1}{8} \lambda^2 - \frac{5}{192} \lambda^3 + \frac{41}{2304} \lambda^4, \quad \nu_1 = \frac{1}{8} \lambda^2 + \frac{7}{192} \lambda^3 - \frac{131}{4608} \lambda^4,$$

$$\mu_2 = \frac{3}{16} \lambda^2 + \frac{7}{48} \lambda^3 + \frac{23}{1024} \lambda^4, \quad \nu_2 = \frac{1}{96} \lambda^3 + \frac{25}{4608} \lambda^4,$$

$$\mu_3 = \frac{5}{64} \lambda^3 + \frac{155}{2304} \lambda^4, \quad \nu_3 = \frac{23}{2304} \lambda^4,$$

$$\mu_4 = \frac{35}{1024} \lambda^4, \quad \nu_4 = 0,$$

and

$$\Lambda(q, \lambda) = \frac{1}{128} \lambda^4 (\cos(2qd) - \cos(2qa)). \tag{10}$$

The terms in $B_c(q, \lambda)$ are consistent with previous publications [8], whereas $B_s(q, \lambda)$ and $\Lambda(q, \lambda)$ contain additional corrections. They originate from a complete expansion of both the ground state $|0\rangle$ and the first excited state $|t\rangle$. If one assumes that $\langle 0 | S_{2i} | t \rangle = - \langle 0 | S_{2i+1} | t \rangle$ for the matrix elements on even and odd sites, one ends up with $B_c(q, \lambda)$ only. However this is only correct to first order and in general we have

‡ Higher order terms are available on request.
\begin{align*}
\langle 0 | S^2_i | t \rangle & \neq -\langle 0 | S^2_{i+1} | t \rangle. \\
\text{This inequality arises from virtual states with odd parity under exchange of two triplets which occur during the perturbation expansion for the first time in second order.}
\end{align*}

In Figure 1 and Figure 2 we show some typical plots of the intensity \( I_{sm}(q) \) for two different ratios \( \sigma = 10/15, \ 10/20 \) and two different coupling strength \( \lambda = 0.4, \ 0.8 \) and strictly linear geometry, \( d \parallel a \) (then, only the component of wavevector in chain direction enters). The difference between the zeroth and the first order emerge very clearly. The higher order terms emphasize the modulation originating from the two length scales \( \| a \| \) and \( \| d \| \).

### 2.2. Sum rule

The total integrated scattering intensity has a well defined magnitude, determined by the local spin length through the following sum rule:

\[
I = \sum_{\alpha} \int dq \int \frac{d\omega}{2\pi} S^{\alpha \alpha}(q, \omega) \int dq = S(S + 1). 
\tag{11}
\]

For the one dimensional alternating chain the contribution from the one-magnon part to the total spectral weight is calculated from eq. (7); the integral reduces to the constant part \( \mu_0 \) of (9), since only non oscillating terms survive the integration:

\[
I_{sm} = \frac{3}{4} \left( 1 - \frac{5}{16} \lambda^2 - \frac{3}{32} \lambda^3 + \frac{25}{1536} \lambda^4 + \ldots \right) \leq \frac{3}{4} \frac{S}{2} = \frac{1}{2}, \quad \lambda \ll 1. 
\tag{12}
\]
For the noninteracting case ($\lambda = 0$) the sum rule is exhausted by the one triplet excitation since it is an exact eigenstate: From (3) we see that this excitation gives the only non-vanishing matrix element. Switching on the coupling between the dimers, more and more intensity goes in two or more magnon scattering processes. A theoretical discussion of the multimagnon states for the one dimensional alternating chain is given in Refs. [8, 12, 13].

3. The 3D dimer substances KCuCl$_3$ and TlCuCl$_3$

In this section we extend the calculation of singlet-triplet intensities to three dimensional substances such as KCuCl$_3$ and TlCuCl$_3$. These compounds are weakly interacting quantum spin systems which exhibit an excitation gap. Similar to the alternating chain discussed in the previous section this is based on the existence of strongly interacting bonds forming dimers. In these materials the orientation af the dimers alternates, i.e. each unit cell consists of four spins with two differently oriented dimers.

The following considerations are valid for dimer systems composed of two dimers per unit cell. We write for the Fourier transformed spin operators

$$S_z(q) = \frac{1}{\sqrt{2N}} \sum_n \sum_{k=1}^2 e^{-i q (n+R_k)} \left[ e^{-i \frac{q d_k}{2}} S_z(n+R_k+\frac{d_k}{2}) + e^{i \frac{q d_k}{2}} S_z(n+R_k-\frac{d_k}{2}) \right],$$

(13)

where $n$ denotes the unit cell, $R_k$ the center of the dimer and $d_k$ the separation of the two spins forming the dimer. The first sum in Eq. (13) is taken over all unit cells. In the case of weakly interacting dimers the localized triplet states are replaced by Bloch-like
Table 1. Considered interactions in KCuCl$_3$ (and TlCuCl$_3$). Vectors $g_k$ denote the distances between the dimer centers.

| distance $g_k$ between dimers | Interactions between equivalent spins ($i = j$) | Interactions between non equivalent spins ($i \neq j$) |
|------------------------------|---------------------------------|---------------------------------|
| $g_1 = a$                    | $J_{(100)}$                     | $J'_{(100)}$                    |
| $g_2 = 2a + c$               | $-$                            | $J'_{(201)}$                    |
| $g_3 = a + \frac{1}{2}(b + c)$ | $J_{(1\frac{1}{2}\frac{1}{2})}$ | $J'_{(1\frac{1}{2}\frac{1}{2})}$ |
| $g_4 = a - \frac{1}{2}(b - c)$ | $J_{(1\frac{1}{2}\frac{1}{2})}$ | $J'_{(1\frac{1}{2}\frac{1}{2})}$ |

Table 2. Values of exchange interactions in KCuCl$_3$[5] and TlCuCl$_3$[3]. The intradimer interaction $J$ is given in meV, interdimer interactions are given in units of $J$ for the respective compound.

| exchange constant | KCuCl$_3$ | TlCuCl$_3$ |
|-------------------|-----------|------------|
| $J$               | 4.25 meV  | 5.68 meV   |
| $J_{(100)}$       | 0.00      | 0.06       |
| $J'_{(100)}$      | 0.10      | 0.30       |
| $J'_{(201)}$      | 0.18      | 0.45       |
| $J_{(1\frac{1}{2}\frac{1}{2})}$ | 0.20      | 0.16       |
| $J'_{(1\frac{1}{2}\frac{1}{2})}$ | 0.05      | -0.10      |

triplet modes which propagate due to the interaction network between the dimer units. The details of the explicit calculation of the transition matrix elements for a Bravais dimer lattice are illustrated in Ref. [8].

In Tab. 1 we describe the interaction network listing the basic lattice vectors associated with nonzero interdimer interactions for the materials considered. In Tab. 2 we give the numerical values of the intradimer exchange $J$ (in meV) and of the interdimer exchange interactions (in relative units) for the compounds KCuCl$_3$ and TlCuCl$_3$. (Slightly improved values for KCuCl$_3$ have been determined in [17], the difference, however, is not visible in the Figures 3 and 5 below.)

The different dimer orientations in the unit cell do not affect the dimer lattice directly, i.e. the lowest excitation does not depend on the dimer orientation. But the full translational symmetry is obviously reduced if the dimer sites are distinct by their orientation.

In analogy to phonons in a lattice with a basis there will be two excitation modes. Therefore we use the following zeroth order ansatz for the one triplet wave function, which manifest translational symmetry:

$$|q\rangle^{(0)} = \frac{1}{\sqrt{2N}} \sum_{k=1}^{2} \sum_{n} c_k e^{-i(q\cdot(n+R_k))} |n + R_k\rangle^{(0)}.$$  \hspace{1cm} (14)

The states $|n + R_k\rangle^{(0)}$ denote a triplet at site $n + R_k$ with all the other sites occupied by singlets. We have introduced the coefficient $c_k$ to take into account the different dimer
or directions. The $c_k$'s are determined requiring that $c_1|n+R_1\rangle + c_2|n+R_2\rangle$ is diagonal in the subspace of the one triplet excitations. Two solutions ($\pm$) are obtained:

\[(c_1^+, c_2^+) = (1, 1) \quad \text{or} \quad (c_1^-, c_2^-) = (1, -1).\]

The solution $c^-$ is connected to umklapp scattering where $q \rightarrow q + u$. Umklapp processes are possible in KCuCl$_3$ and TiCuCl$_3$ with an integer number of the reciprocal lattice vector $u = b^*$ or $u = c^*$.

The resulting energies are denoted by $\omega^\pm(q)$ where we describe both modes in the first crystallographic Brillouin zone. Up to first order we obtain the well known dispersion relation [5, 4] in units of $J$:

\[\omega^\pm(q) = 1 + 2 \sum_{i=1}^2 \beta_i \cos(g_i q) \pm 2 \sum_{i=3}^4 \beta_i \cos(g_i q) + O(\lambda^2).\]  

Here and in the following we use some short-hands of various combinations of coupling constants ($\epsilon_i$ and $\gamma_i$ will be needed for the intensity calculation below):

\[
\begin{align*}
\beta_1 &= \frac{1}{4}(2J_{(100)} - J'_{(00)}), & \epsilon_1 &= \frac{1}{4}(2J_{(100)} + J'_{(00)}), & \gamma_1 &= \frac{1}{4}J'_{(00)}, \\
\beta_2 &= -\frac{1}{4}J'_{(201)}, & \epsilon_2 &= \frac{1}{4}J'_{(201)}, & \gamma_2 &= -\frac{1}{4}J'_{(201)}, \\
\beta_3 &= \frac{1}{4}(J_{(1\frac{1}{2} \frac{1}{2})} - J'_{(1\frac{1}{2} \frac{1}{2})}), & \epsilon_3 &= \frac{1}{4}(J_{(1\frac{1}{2} \frac{1}{2})} + J'_{(1\frac{1}{2} \frac{1}{2})}), & \gamma_3 &= \frac{1}{4}(\pm J_{(1\frac{1}{2} \frac{1}{2})} + J'_{(1\frac{1}{2} \frac{1}{2})}), \\
\beta_4 &= \beta_3, & \epsilon_4 &= \epsilon_3, & \gamma_4 &= \gamma_3. 
\end{align*}
\]

To obtain the transition matrix element one has to expand both the ground state and the one triplet state perturbatively in the coupling constants. To indicate the order we take all interdimer couplings proportional to a constant $\lambda$.

### 3.1. The ground state

There are four different directions $g_i$ in which we find interdimer interactions (see Tab. 1). As well as in the one dimensional case the unperturbed ground state is a product of singlets placed on the rungs:

\[|G\rangle^{(0)} = \prod_n |s_{n+R_1}\rangle |s_{n+R_2}\rangle = |S\rangle.\]  

Due to the different orientations we distinguish between singlets at $n + R_1$ and $n + R_2$. Up to the second order the ground state including all relevant states for the structure factor is

\[|G\rangle^{(2)} = \alpha_0|S\rangle + \frac{\sqrt 3}{2} \sum_{i=1}^4 \sum_{k=1}^2 \sum_{n} \beta_i(1 + \epsilon_i)|n+R_k, n+R_k+g_i\rangle^{(0,0)} \]

\[+ \frac{\sqrt 3}{2} \sum_{i,j=1}^4 \sum_{k=1}^2 \sum_{n} \beta_i \beta_j|n+R_k, n+R_k+g_i+g_j\rangle^{(0,0)} \]

\[+ \frac{\sqrt 3}{2} \sum_{i,j=1}^4 \sum_{k=1}^2 \sum_{n} \beta_i \beta_j|n+R_k, n+R_k+g_i-g_j\rangle^{(0,0)} \]
Dynamical Structure Factors for Dimerized Spin Systems

+ states with three or four triplet excitations. \( (22) \)

The indices \( i,j \) are linked to the different interaction directions and \( k \) counts the two dimer sites in the elementary cell. We further denote the states having two triplets at sites \( r \) and \( r' \) with well-defined \( S_{\text{tot}} \) and \( S_{\text{tot}}^z \) by \( |r,r' \rangle^{(S_{\text{tot}},S_{\text{tot}}^z)} \). \( \alpha_0 \) is a normalization factor which guarantees that \( \langle G|G \rangle^{(2)} = 1 + \mathcal{O}(\lambda^3) \):

\[
\alpha_0 = 1 - \frac{3}{4} N \sum_{i=1}^{4} \beta_i^2.
\]

(23)

Note that \( N \) labels the number of unit cells, whereas \( 2N \) is the number of dimers in the system.

3.2. One triplet excitation

The expansion of the wave function for the one triplet excitation in the interdimer interactions is obtained to first order by acting with the Hamiltonian \( \mathcal{H}_1 \) on the state (14) and some subsequent normalization. In addition to simple propagation of the triplets this leads to the generation of two triplet excitations \( |r,r' \rangle^{(1,0)} \) where \( (S_{\text{tot}},S_{\text{tot}}^z) = (1,0) \) is the total spin and total magnetization and \( r, r' \) label the lattice sites occupied by triplets. There are also three triplet excitations with the same spin quantum numbers. Second order terms contribute to the third order\(^\S \) of the intensity only and will not be calculated here. However, normalization of the wave function has to be done up to second order terms.

3.3. The dynamical structure factor

To leading order one expects a dimer-like structure factor as in Sec. 2. In fact there are two different contribution due to the two dimer structure in the elementary cell:

\[
I_\pm(q) = D_\pm^2(q) + \mathcal{O}(\lambda^1) = \left[ \sin \frac{qd_1}{2} \pm \sin \frac{qd_2}{2} \right]^2 + \mathcal{O}(\lambda^1).
\]

(24)

The indices \( \pm \) refer to (16) and correspond to symmetric resp. antisymmetric modes for \( q \) in the first Brillouin zone. However, the role of symmetric and antisymmetric modes is interchanged for \( q \rightarrow q + \tau \) where \( e^{i\tau (R_2-R_1)} = -1 \). From now on \( q \) stays in the first Brillouin zone.

The representation of (24) is instructive in order to emphasize that in general there are contributions from two different modes for a wavevector \( q \) in the crystallographic Brillouin zone. The total contribution

\[
I_+(q) + I_-(q) = 2 \sin^2 \frac{qd_1}{2} + 2 \sin^2 \frac{qd_2}{2}
\]

(25)

reproduces correctly the structure factor \( \int d\omega S(q,\omega) \) as calculated from (1) in lowest order.

\(^\S \) All contributing terms can be obtained on request.
A finite contribution for the excitation mode with energy \( \omega^- (q) \) requires \( q d_1 \neq q d_2 \). Taking into account the dimer orientations \( d_{1,2} \) where
\[
d_1 = 0.48a + 0.10b + 0.32c, \\
d_2 = 0.48a - 0.10b + 0.32c
\]we deduce the condition \( q_b \neq 0 \), in agreement with the experimental observations.

Considering higher order corrections to the ground state and the first excited state as presented below, we get the following result valid up to second order:
\[
I_{\pm}(q) = \frac{1}{4} D_{\pm}^2(q)(1 - \Omega_{\pm}(q) + \Omega_{\pm}^2(q) - \Sigma_{\pm}(q) - \Sigma_1(q)) + \frac{1}{2} D_{\pm}(q)(\cos \frac{q d_1}{2} \pm \cos \frac{q d_2}{2}) \Delta_{\pm}(q)
\]
where
\[
\Omega_{\pm}(q) = 2 \sum_{i=1}^{2} \beta_i \cos(q g_i) \pm 2 \sum_{i=3}^{4} \beta_i \cos(q g_i), \\
\Sigma_{\pm}(q) = \sum_{i=1}^{4} \left[ 3 \beta_i^2 - \beta_i^2 \cos(2q g_i) \right] + 2 \sum_{i=1}^{2} \beta_i \varepsilon_i \cos(q g_i) \pm 2 \sum_{i=3}^{4} \beta_i \varepsilon_i \cos(q g_i), \\
\Sigma_1(q) = 4 \sum_{i=1}^{2} \gamma_i^2 [1 + \cos(q g_i)] + 2 \sum_{i=3}^{4} \left[ \gamma_i^2 + \gamma_i^{-2} + 2 \gamma_i^+ \gamma_i^- \cos(q g_i) \right], \\
\Delta_{\pm}(q) = 2 \sum_{i=1}^{2} \beta_i \gamma_i \sin(q g_i) + 2 \sum_{i=3}^{4} \beta_i (\gamma_i^\pm \pm \gamma_i^\mp) \sin(q g_i)
\]
The dynamical structure factor contains contributions from both excitation modes:
\[
S^{zz}(q, \omega) = I_+(q) \delta(\omega - \omega^+(q)) + I_-(q) \delta(\omega - \omega^-(q))
\]
where \( \omega^\pm(q) \) denotes the one triplet excitation energy as in (16). We note that \( \Omega(q) \) is the energy of the one triplet excitation \( \omega^+(q) \) up to first order. If we neglect the terms \( \Sigma_1(q) \) and \( \Delta_{\pm}(q) \) the result reduces to RPA-like calculations [9] where \( I_{\pm}(q) \propto 1/\omega^\pm(q) \).

In order to demonstrate the effect of interdimer interactions on the dynamical structure factor we show in Figure 3 theoretical results for KCuCl\(_3\) (top panel) and TlCuCl\(_3\) (bottom panel) in 0\(^{th}\) (noninteracting dimers), 1\(^{st}\) and 2\(^{nd}\) order, exchange parameters are taken from Tab. 2. As in the INS experiments to be discussed in the next subsection and as in Ref. [9], the variation of the spectral weight of the triplet excitation \( I_+ + I_- \) with wave vector is shown along the \((0, x, x)\) direction of reciprocal space, such that both modes contribute with finite weight. Evidently, higher order corrections are more important for TlCuCl\(_3\) with its larger exchange constants, but even for these larger values the comparison of different orders seems to indicate convergence. Exhaustive experimental results for both \( I_+ \) and \( I_- \) are available for KCuCl\(_3\) and will be discussed in the next subsection. Clearly, devoted INS experiments for TlCuCl\(_3\) are of considerable interest (see also [4] and [3]); the ratio of spectral weights at wave vectors corresponding to maximum and minimum intensity appears to be a reasonable quantity.
to test the agreement with our theoretical results. Present results do not indicate that higher than 2nd order calculations are required.

3.4. Experiment

The INS results on the material KCuCl$_3$ were collected at the IN3 neutron spectrometer, Institut Laue-Langevin, Grenoble (France). Standard focusing geometry was adopted for all energy scans performed under constant final energy $E_f = 13.7$ meV. A pyrolitic graphite (PG) filter in front of the analyser was further used to suppress higher order contaminations.
The INS profiles were obtained at fixed $T = 2\text{K}$ for the wave vectors along the $(0, x, x)$ direction of reciprocal space, which is suited to demonstrate the issues introduced above. For this purpose, a KCuCl$_3$ single crystal was aligned for scattering in the $b^*c^*$ plane. The spectral weight of the triplet excitation was determined from global least squares fits to the measured neutron profiles, assuming gaussian peaks on top of a common background. The center of the peaks was further fixed at the energies $\omega^\pm(q)$ resulting from the analysis presented in Ref. [5]. (see Tab. 2) Our present results complete the experimental investigation of the $b^*c^*$ plane summarized in Ref. [4], and references therein.

In Figure 4 typical fits of the neutron profiles are shown for wave vectors $q$ at selected $(0, x, x)$ values, in reciprocal lattice units (r.l.u.) of the unit cell. In accordance with the theoretical expectations, both excitation modes $\omega^\pm(q)$ are visible along $(0, x, x)$ but the spectral weight $I^\pm(q)$ strongly depends on $x$. Continuous lines denote the global least squares fit function, symbols the profiles in neutron counts. The statistical tolerance scales according to the neutron counts. In Figure 5, the fitted spectral weight is compared to the model expectations previously introduced. In the top panel, the total spectral weight $F^2(I_+ + I_-)$ (full line) is compared to the experimental observations (symbols). The only free parameter is an overall scaling factor accounting for the size of the sample, both the plain calculation (dashed dotted line, second order) and the
**Figure 5.** Spectral weight of the triplet excitation for KCuCl$_3$ along the (0, x, x) direction in reciprocal space. Symbols indicate experimental data from least squares fit to the profiles. Top panel: theoretical result for $F^2(I_+ + I_-)$ in second order (full line) and for noninteracting dimers (dashed line), $F^2$ (dotted line) and $(I_+ + I_-)$ in second order (dash-dotted line). Bottom panel, full line: theoretical result in second order for the relative spectral weight.

Squared magnetic form factor $F^2$ (dotted line) [14] are shown separately for convenience. In the bottom panel, the relative spectral weight $I_+/(I_+ + I_-)(q)$ is compared to the experimental observations, as indicated. The graphical representation underlines the redistribution of the spectral weight among $I_+$ and $I_-$ which occurs along the (0, x, x) direction of reciprocal space.

From Figure 5, reasonable agreement between predictions from the dimer model and experimental results is concluded. The spectral weight is dominated by the bipartite
Dynamical Structure Factors for Dimerized Spin Systems
dimer structure, which governs the result in the noninteracting dimer limit, but the
existence of higher order corrections is clearly seen close to the second maximum ($x \approx 3$).
Details of higher order corrections remain almost beyond statistics for KCuCl$_3$ but
may become more pronounced in the sister material TlCuCl$_3$. Our results improve
on the previous RPA calculations [9] which are correct only to first order. Related
investigations along different directions of the $b^*c^*$ plane were successfully compared to
RPA calculations in Ref. [15]. The relative spectral weight (bottom panel of Figure 5) is
very well described already in the noninteracting dimer picture (not shown in Figure 5),
higher order corrections are below statistical significance for this quantity.

3.5. Sum rule

We calculate the one magnon contribution to the total integrated scattering intensity in
order to check the sum rule (12). As seen in (32) the dynamical structure factor consists
of two parts. Integrating over $q$, only non oscillating terms survive, giving

$$I_{sm} = \frac{3}{4} \left[ 1 - \sum_{i=1}^{4} \beta_i^2 - 4(\gamma_1^2 + \gamma_2^2) - 2(\gamma_3^2 + \gamma_4^2 + \gamma_5^2 + \gamma_6^2) \right] + O(\lambda^3).$$

Using the coupling constants as calculated in Ref. [5] we estimate here the intensity
which goes into higher order scattering processes like two or more magnon scattering.
We obtain $I_{sm} = 0.7217$ which means that 96.23% of the total scattering intensity is
concentrated in the lowest triplet excitation. Although the interactions in TlCuCl$_3$ are
more pronounced most of the scattering intensity still goes in the one magnon process
which is reflected by inserting calculated coupling constants [3] in (33): $I_{sm} = 0.7021$
or 93.62% respectively. The absolute experimental determination of the spectral weight
from dimers is exemplified in Ref. [16], but a devoted investigation of the materials
KCuCl$_3$ and TlCuCl$_3$ has not been performed up to now.

4. Conclusion

We have presented series expansions for the dynamical structure factor valid generally
for lattices with two dimers per unit cell. Applying our results to the interacting dimer
material KCuCl$_3$, we have shown that results obtained by inelastic neutron scattering
are reasonably well described by the theoretical calculations. Our expressions apply
as well to the sister material TlCuCl$_3$, which shares with KCuCl$_3$ the structure of the
exchange couplings, but has larger exchange strengths. For the specific direction in
$q$-space considered here our results show that higher order terms are not relevant for
relative spectral weights (see Figure 5 as measured in KCuCl$_3$ with present intensity)
and we expect that this is generally true. Second order shifts, however, show up in
absolute spectral weights [17], most clearly in TlCuCl$_3$.

The materials KCuCl$_3$ and TlCuCl$_3$ recently have been demonstrated to undergo
field-induced magnetic ordering. The evolution of the excitation modes at finite
magnetic field has been described in a comprehensive theoretical study [18], albeit limited to the energy of the excitations. Theoretical investigations of the spectral weight in an external magnetic field are now under preparation.

Appendix A. Cluster Expansion

In this appendix we briefly summarize the method of cluster expansion for the dynamical structure factor in the case of the alternating chain. Some detailed considerations can be found elsewhere [19]. As shown in Figure A1 the cristallographic unit cell contains two spins. Thus the Fourier transform of the spin operator splits into two parts and reads as:

\[ S^\alpha(q) = \sum_n e^{-iqa} \left( e^{-i\frac{qd}{2}} S_1^\alpha(n) + e^{i\frac{qd}{2}} S_2^\alpha(n) \right). \]  

(A.1)

As before \( |a| = a \) is the distance between neighbouring spins and \( d \) denotes the spacing between the two spins on a dimer. In our notation \( q \) is the projection of the wave vector \( q \) on the chain direction.

Using translational invariance with respect to the center of the dimer we obtain for the singlet-triplet transition amplitude:

\[ I_{sm}(q) = \sum_n e^{-iqa} \left[ A_{11}^{zz}(n) + A_{22}^{zz}(n) + e^{iqd} A_{12}^{zz}(n) + e^{-iqd} A_{21}^{zz}(n) \right] \]  

(A.2)

where \( A_{ij}^{zz}(n) = \langle 0|S_i^z(0)|t\rangle \langle t|S_j^z(n)|0\rangle, \quad i, j = 1, 2. \)  

(A.3)

Here, the sum is taken over all integer numbers \( n \). However, it is more convenient to calculate the functions \( A_{ij}^{zz}(n) \) for positive numbers \( n \). This is feasible making use of inversion symmetry wrt to the dimer center, implying

\[ A_{11}^{zz}(-n) = A_{22}^{zz}(n) \quad \text{and} \quad A_{12}^{zz}(-n) = A_{21}^{zz}(n). \]  

(A.4)

Inserting (A.4) into (A.2) one arrives at the following result:

\[ I_{sm}(q) = 2 \sum_{n>0} (A_{11}^{zz}(n) + A_{22}^{zz}(n)) \cos(qna) \]  

(A.5)

\[ + 2 \sum_{n>0} (A_{12}^{zz}(n) \cos(qna - qd) + A_{21}^{zz}(n) \cos(qna + qd)) \]  

(A.6)
Now, functions $A_{ij}^{zz}(n)$ enter for positive $n$ only. In the limit of noninteracting dimers only the terms with $n = 0$ (last line) survive.

At first glance the functions $A_{ij}^{zz}(n)$ are groundstate expectation values which can be computed by the well established cluster expansion method [20]. The projection operator $P = |t⟩⟨t|$ has to be evaluated from the one magnon states $|ψ^{(i)}⟩$, where $i$ labels the lattice site. By means of degenerate cluster expansion these states are generated order by order [21]. Then we find for projection operator:

$$P = |1⟩⟨1| = \sum_{ij} (g^{-1})_{ij} |ψ^{(i)}⟩⟨ψ^{(j)}|.$$  \hspace{5cm} (A.8)

$g$ is the overlapping matrix of the $|ψ^{(i)}⟩$:

$$g_{ij} = ⟨ψ^{(i)}|ψ^{(j)}⟩.$$  \hspace{5cm} (A.9)

To invert $g$ we use the fact that $g$ is the unit matrix for $λ \rightarrow 0$:

$$g = I + \tilde{g}.$$  \hspace{5cm} (A.10)

Owing to the matrix norm $\|\tilde{g}\| < 1$ we apply a geometric series to invert $g$:

$$(I + \tilde{g})^{-1} = \sum_{i=0}^{∞} \tilde{g}^i.$$  \hspace{5cm} (A.11)

Now we have everything at hand to calculate the singlet-triplet-intensity of the dynamical structure factor: Apply degenerate perturbation theory to obtain the states $|ψ^{(j)}⟩$ and $P$. Then calculate $g$ and invert this matrix by using (A.11). Finally, apply non degenerate perturbation theory to compute the functions $A_{ij}^{zz}(n)$.
