Learning Point of the Article:
Early recognition and intervention are needed with preoperation templating for successful outcomes in cases with complex injuries.

Abstract

Introduction: High-energy trauma has increased the incidence of traumatic hip dislocation. In most cases, dislocation of the hip is associated with fractures of the acetabulum. However, its association with ipsilateral intertrochanteric fracture is very rare.

Case Report: We present a case of a 54-year-old male who had uncommon fracture pattern involving ipsilateral intertrochanteric femur fracture associated with ipsilateral posterior fracture dislocation of hip following a road traffic accident. He underwent closed reduction of the dislocation followed by an open reduction and internal fixation of the fractures. Through Kocher-Langenbeck approach, the intertrochanteric fracture was reduced and fixed with dynamic hip screw and derotation anti-rotation screw. Acetabulum fractures then fixed after reduction with two reconstruction plates.

Conclusion: Early recognition and orthopedic intervention constitute the cornerstones of satisfactory outcomes in cases with such complex injuries.

Keywords: Posterior hip dislocation, acetabular fractures, intertrochanteric fracture.

Case Report

A 54-year-old male was admitted to our hospital in October 2019 after a road traffic accident. On admission, he was conscious (Glasgow Coma Scale = 15) and hemodynamically stable. He had severe pain in the right knee and was unable to move his right leg. On examination, his right leg was 2 cm shortened and rotated internally. Skin overlying the right patella had an open wound. Vascular and neurological examinations were normal. Examination of other limbs showed no injury. After primary stabilization of the patient as per advance trauma life support...
Postoperatively, the patient started inpatient physiotherapy immediately after surgery, then, he was discharged to complete a planned outpatient physiotherapy. That is, hip joint mobilization exercises were started at 3 weeks after surgery and walking without weight-bearing on the left lower limb was followed at 6 weeks after surgery. Progressive weight-bearing of the injured limb is allowed at 3 months after surgery (Fig. 4).

At the end of 1 year, the patient had painless hip with full range of motion. No radiological signs of avascular necrosis have been seen by the end of 1 year.

Immediately after resuscitation, the right hip dislocation was reduced in the emergency department with axial traction and gentle manipulation. Reduction was maintained with skin traction. Repeated post-reduction images (Fig. 2-4) showed no intra-articular fragments or loose bodies in the hip joint.

The procedure done through one approach. Acetabulum fractures fixation addressed after fractures reduction, then fixed with two reconstruction plates (Fig. 3). No drain was used postoperatively. Injuries of the knee were treated by debridement and primary closure.

Postoperatively, the patient started inpatient physiotherapy immediately after surgery, then, he was discharged to complete a planned outpatient physiotherapy. That is, hip joint mobilization exercises were started at 3 weeks after surgery and walking without weight-bearing on the left lower limb was followed at 6 weeks after surgery. Progressive weight-bearing of the injured limb is allowed at 3 months after surgery (Fig. 4).

Discussion

Road traffic accident is the leading cause of traumatic hip dislocation. Furthermore, posterior hip dislocation is reported more frequent than the anterior type [3]. Majority of patients with traumatic hip dislocations have severe associated injuries in as many as 40–75% of them, mostly head and visceral injuries, contralateral femur fractures, ipsilateral leg and knee injuries, and upper limb injuries [8]. In a large number of traffic accident cases, the right side of the vehicle is more involved in the crash; therefore, the right hip is predominantly injured [9].

The initial treatment of a patient with a dislocated hip is the same treatment for a patient with polytrauma. Life-threatening injuries must be addressed and stabilized first; however, the hip dislocation is an orthopedic emergency that requires immediate evaluation and reduction to avoid further complications. In general, open reduction and internal fixation of the acetabular fracture is best done in the first 10 days after injury [10]. Surgical treatment of the acetabular fracture has to be delayed in some patients because of associated injuries.

We described a case of a complex fracture pattern involving ipsilateral intertrochanteric fracture associated with ipsilateral posterior hip dislocation and posterior acetabular wall fracture. Few similar cases have been described in the literature [4, 5, 6, 7]. Up to now, such a fracture pattern has not been explained by the classification systems described for hip dislocation injuries [11, 12].

In our case, through Kocher-Langenbeck, we performed open reduction and fixation for intertrochanteric, posterior acetabular wall, and posterior column fractures in one session of surgery. Avascular necrosis of the femoral head, post-traumatic osteoarthritis, heterotopic ossification around the joint, and...
With the increase in high-energy trauma and associated injuries, early recognition and intervention are needed for successful outcomes in cases with such complex injuries. Pre-operative planning is of high importance to achieve satisfactory results, as in our case, the surgeon addressed many fractures using a single approach in one-stage operation.

Paralysis of the sciatic nerve are the main complications that can occur following hip dislocation with acetabular fractures [3, 13, 14].

On the follow-up of the patient, he did not get avascular necrosis of the femoral head, could be due to the early intervention. As the time passed between the initial trauma and reduction directly influences the incidence of avascular necrosis. Hougaard and Thomsen reviewed 98 patients with 100 dislocations after a minimum follow-up of 5 years to clarify the prognostic factors influencing the incidence of avascular necrosis of the femoral head. They observed the development of avascular necrosis in 4.8% of the hips reduced within 6 h and in 52.9% of the hips reduced more than 6 h after the injury [15].

The risk of developing AVN may also increase by performing an open reduction for the hip joint dislocation [6].

The sciatic nerve injury is common in traumatic posterior hip dislocations associated with displaced posterior acetabular fractures which have been reported to occur in 10–13% of patients [16].

Conclusion

With the increase in high-energy trauma and associated injuries, early recognition and intervention are needed for successful outcomes in cases with such complex injuries. Pre-operative planning is of high importance to achieve satisfactory results, as in our case, the surgeon addressed many fractures using a single approach in one-stage operation.

Clinical Message

The rapid evaluation and treatment are crucial in the management of such cases to avoid significant long-term morbidity.
