MEC-2 and MEC-6 in the Caenorhabditis elegans Sensory Mechanotransduction Complex: Auxiliary Subunits that Enable Channel Activity

Austin L. Brown, Zhiwen Liao, and Miriam B. Goodman

INTRODUCTION

Sensing force is ubiquitous in cellular life, with uses ranging from protection from osmotic shock in bacteria (Levina et al., 1999) to the appreciation of the softest touch on human skin (Johansson and Vallbo, 1979). Among medically relevant modes of force transduction in humans are flow regulation in the kidney, blood pressure regulation in vasculature, hearing, proprioception in musculature, nociception, and cutaneous touch. Each of these processes is likely to involve many molecules that have proven difficult to identify, possibly due to their rarity. In contrast, genetic analysis of touch in Caenorhabditis elegans has proven fruitful for identifying the molecular components of mechanotransduction machinery, including four membrane proteins (MEC-2, MEC-4, MEC-6, and MEC-10). These proteins form amiloride-sensitive, Na⁺-selective sensory mechanotransduction channels in the touch receptor neurons (TRNs) responsible for detecting low-intensity touches in C. elegans (O’Hagan et al., 2005). In Xenopus oocytes, these proteins also form amiloride-sensitive Na⁺ channels (Chelur et al., 2002; Goodman et al., 2002a).

MEC-4 and MEC-10 are pore-forming subunits that belong to the superfamily of degenerin/epithelial sodium channel (DEG/ENaC) ion channel proteins that are conserved in metazoans. DEG/ENaC proteins are predicted to share a common topology consisting of two transmembrane helices, intracellular N and C termini, and a large extracellular domain (Kellenberger and Schild, 2002). Recent structural data confirm this topology (Jasti et al., 2007). MEC-2 and MEC-6 are auxiliary subunits required for channel function in vivo (O’Hagan et al., 2005). Replacing the wild-type alanine at the degenerin (d) position in MEC-4 (A713) or MEC-10 (A673) with residues larger than cysteine induces TRN degeneration in vivo (Driscoll and Chalfie, 1991; Huang and Chalfie, 1994) and increases channel open probability in Xenopus oocytes (Brown et al., 2007). The d position is at the extracellular end of the second transmembrane domain and its side chain interacts with the first transmembrane domain of the adjacent subunit (Jasti et al., 2007). This structural observation is consistent with our finding that mutations at the d position in MEC-10 can both enhance and suppress gain-of-function mutations in MEC-4 (Brown et al., 2007). Taking advantage of the increased open probability in mutants, we study gain-of-function mutants of both MEC-4 and MEC-10 with an alanine to threonine substitution at the d position. For clarity, we refer to these mutants as MEC-4d and MEC-10d and to heteromeric channels as MEC-4d/10d channels.

Abbreviations used in this paper: DEG, degenerin; ENaC, epithelial sodium channel; HDL, high-density lipoprotein; PHB, prohibitin homology; PON, paraoxonase; TRN, touch receptor neuron.
Defects in the genes encoding MEC-2 and MEC-6, which are coexpressed with MEC-4 and MEC-10 in TRNs (Lai et al., 1996; Chelur et al., 2002; Goodman et al., 2002a), suppress degeneration (Chalfie and Wolinsky, 1990; Huang and Chalfie, 1994), suggesting that these proteins might be critical for channel function. Consistent with this idea, MEC-2 and MEC-6 dramatically enhance macroscopic currents carried by heteromeric MEC-4d/10d channels in Xenopus oocytes without increasing the expression of either protein in the plasma membrane. Together, MEC-2 and MEC-6 increase macroscopic current by more than 100-fold (Chelur et al., 2002; Goodman et al., 2002a). It is not known how these auxiliary proteins achieve their remarkable effect without increasing surface expression. All available evidence suggests that the effects of MEC-2 and MEC-6 on current are similar in wild-type and degenerin mutant channels (Chelur et al., 2002; Goodman et al., 2002a). Under this assumption, we use mutant channels with increased open probability to facilitate measurement of the effects of auxiliary subunit coexpression.

Like some other prohibitin-homology (PHB) domain proteins (SMART database; http://smart.embl-heidelberg.de), MEC-2 is associated with the inner leaflet of the plasma membrane and does not cross the bilayer (Huang et al., 1995). In its central PHB domain, MEC-2 is 65% identical to human stomatin and 62% identical to SLP-3. In mice, both stomatin and SLP-3 are expressed in the cell bodies and nerve terminals of dorsal root ganglion sensory neurons (Mannsfeldt et al., 1999; Wetzel et al., 2007). Loss of stomatin reduces the response of a single class of somatosensory neurons to mechanical stimuli (Martínez-Salgado et al., 2007). SLP-3 is required in several classes and also plays a critical role in texture discrimination (Wetzel et al., 2007). MEC-2 binds the N-terminal domain of MEC-4 through its central PHB domain (Zhang et al., 2004a). MEC-2 is palmitoylated and binds cholesterol directly (Huber et al., 2006). The double-cysteine mutant MEC-2 (C140/174A) is no longer palmitoylated and has reduced cholesterol-binding activity (Huber et al., 2006). MEC-2 (P134S), which recapitulates the u274 allele of the mec-2 gene, fails to bind cholesterol in vitro, but localizes to the plasma membrane in HEK293T cells and binds to DEG/ENaC proteins (Huber et al., 2006). Considered together with the finding that mec-2(u274) animals are touch insensitive, these data suggest that cholesterol binding is required for normal MEC-2 activity. Both palmitoylation and cholesterol binding are likely to fine tune the association between MEC-2, the pore-forming subunits MEC-4 and MEC-10, and the plasma membrane and may recruit specialized lipid microdomains to the vicinity of the MEC-4 channel. MEC-2 is not the only PHB protein likely involved in C. elegans touch sensation. UNC-24 is coexpressed with MEC-2 in the TRNs (Zhang et al., 2004a,b) and several PHB proteins, including UNC-24, appear to associate with cholesterol-rich, detergent-resistant membrane fractions (Sedensky et al., 2004).

With a short cytoplasmic N terminus and a single transmembrane domain, the majority of the MEC-6 protein is extracellular (Chelur et al., 2002). In its extracellular domain, MEC-6 is homologous to human paraoxonase (PON1), an enzyme that hydrolizes organophosphates and has a role in preventing heart disease through its association with high-density lipoprotein (HDL) particles (Draganov et al., 2000). By structural and functional criteria, several residues in PON1 are believed to be important for enzymatic activity (Harel et al., 2004; Yeung et al., 2005). Only one of these residues is conserved in MEC-6, N143, suggesting that MEC-6 lacks enzymatic activity. Association between PON1 and HDL particles is believed to involve two amphipathic helices, one of which is proposed to extend hydrophobic aromatic residues into the lipid interface (Harel et al., 2004). This domain, including a series of aromatic residues arranged along one side of the helix, is conserved in MEC-6 (unpublished data) and may facilitate association between MEC-6 and the outer leaflet of the plasma membrane. Wild-type MEC-6 is required for proper localization of the channel complex in vivo but not in oocytes (Chelur et al., 2002). Thus, MEC-6 has at least two roles, only one of which is recapitulated in heterologous cells.

Among known regulators of ENaC activity are various serine proteases. There is a growing body of evidence that proteases can modify ENaC activity in diverse ways (for review see Planes and Caughey, 2007). For example, furin seems to be involved in post-translational processing in the endoplasmic reticulum (Hughey et al., 2004), membrane-bound channel-activating proteases (CAPs) regulate the channel after insertion into the membrane (Vallet et al., 2002), and soluble proteases such as trypsin activate channels dwelling in a near-silent state (Caldwell et al., 2004), though it has been suggested that this activation may be indirect (Bengrine et al., 2007).

Here, we use mutations at the d position to render channels constitutively active in Xenopus oocytes and use single-channel, macropatch, and whole-cell recording to investigate the mechanism by which the auxiliary subunits MEC-2 and MEC-6 enhance channel activity. We explore the roles of MEC-2 and MEC-6 in block by divalent ions, sensitivity to proteases, single-channel properties, and surface expression. Finally, we demonstrate that MEC-2 and MEC-6 have a role in promoting an active state of the channel and show that this activity is lost in MEC-2 mutants deficient in cholesterol binding.

MATERIALS AND METHODS

Molecular Biology
Constructs encoding full-length MEC-4d and MEC-10d as well as myc-tagged MEC-4d were propagated in SMC4 bacteria (American
Type Culture Collection accession no. PTA-4084) as previously described (Goodman et al., 2002a; Brown et al., 2007). Constructs encoding full-length, wild-type MEC-2 and MEC-6 were propagated in XL1-Blue. MEC-2 mutants were obtained by in vitro mutagenesis (Quik-Change Kit, Invitrogen).

**Heterologous Expression**

Capped cRNAs were synthesized in vitro (mMESSAGE mMACHINE T7 kit, Ambion) and quantified spectroscopically. *Xenopus laevis* oocytes were isolated and injected with 50 nl of cRNA solution. Except where indicated, we injected equal amounts of MEC-4d, MEC-10d, and MEC-2 cRNA and one tenth that amount of MEC-6 cRNA. (Larger amounts of MEC-6 cRNA induce a non-specific, amiloride-insensitive current that complicates analysis (Chelur et al., 2002).) Oocytes were maintained at 18°C in modified L-15 medium supplemented with gentamicin (144 μM) and amiloride (500 μM) until recording.

Injection conditions were modified according to the experimental goal. For whole-cell recordings or macropatches with many active channels, 2.5–5 ng of MEC-4d cRNA was injected. For single channel recordings, both the amount of cRNA injected and days of incubation were optimized to maximize the chance of obtaining single-channel patches. With MEC-2 and MEC-6 present, less cRNA and shorter incubations were required to obtain a similar channel density. For single-channel recordings, conditions were (a) for MEC-4/10d alone, 5–10 ng each, 4–10 d; (b) for MEC-4d/10d + MEC-2, 2–5 ng each, 2–4 d; (c) for MEC-4d/10d + MEC-6, 1–2 ng each, 5–6 d; (d) for MEC-4d/10d + MEC-2 + MEC-6, 0.25–1 ng each, 1–2 d.

**Electrophysiology: Whole-Cell Recording**

Membrane current was measured by two-electrode voltage-clamp (OC-725C, Warner Instruments, LLC) at room temperature (21–24°C). Electrodcs (1–4 MΩ) were fabricated on a horizontal puller (P-97; Sutter Instruments) and filled with 3 M KCl. Analogue signals were filtered at 200 Hz (8-pole Bessel filter) and sampled at 1 kHz. A 60-Hz notch filter was used to minimize line noise. Oocytes were superfused with control saline containing (in mM) Na-glucosinate (100), KCl (2), MgCl₂ (2), CaCl₂ (1), and Na₂ EGTA (10), adjusted to pH 7.4 with NaOH. The amplitude of noise. Oocytes were maintained at 18°C in modified L-15 medium supplemented with gentamicin (144 μM) and amiloride (500 μM) until recording.

**Electrophysiology: Outside-Out Patches**

Vitelline membranes were removed from oocytes manually following incubation in a hypertonic solution composed of (in mM) NMDG-aspartate (220), MgCl₂ (1), EGTA (10), KCl (2), HEPES (10), and amiloride (0.3), adjusted to pH 7.4 with NMDG. Pipettes (2–8 MΩ) were pressure polished (Goodman and Lockery, 2000) and filled with a calcium-buffered saline solution containing (in mM) Na-glucosinate (100), NaCl (2), CaCl₂ (2), Na₂EGTA (5), and HEPES (10), adjusted to pH 7.4 with NaOH. External solutions were identical to pipette solution, except where Ca²⁺ (1–10 mM), Mg²⁺ (1–10 mM), or amiloride (50 μM) were added. Where divalent ions were added, Na₂EGTA was omitted from external solution. Single-channel and macropatch currents were recorded in an outside-out configuration with a patch-clamp amplifier (WPC-100 E.S.F.; Bioscience Tools), filtered (f = 1–5 kHz, 4-pole Bessel filter), and digitized at a rate that was at least three times the filtering frequency. Pulse/Pulsefit or Patchmaster software (HEKA Electronics Inc.) was used to control data acquisition. Igor Pro (WaveMetrics) and Qub Software (The Research Foundation of the State University of New York; http://www.qub.buffalo.edu) were used for single-channel data analysis. Single-channel conductance and open probability were calculated from all-points histograms derived from leak-subtracted records that were 4.7 min long on average. We corrected for non-specific leak currents by fitting a line to time intervals in which all channels were closed and subtracting the result from the data.

**MEC-4 Surface Expression**

Analysis of surface protein closely followed methods described previously (Chillaron et al., 1997; Goodman et al., 2002a). Between 100 and 150 intact oocytes were selected 4 d after cRNA injection, placed in a Petri dish coated with agarose (1% wt/vol in OR-2) and washed three times in OR-2 medium (82.5 mM NaCl, 2.5 mM KCl, 1 mM MgCl₂, 5 mM HEPES adjusted to pH 7.6 with NaOH). Surface proteins were labeled by incubating oocytes in OR-2 medium containing membrane-impermeant reagent EZ-Link Sulfo-NHS-LC-Biotin (Pierce Chemical Co., 16 mg/ml) for 10 min. The reaction was stopped by adding 2 ml of 500 mM glycine, pH 7.5 (1 min), and washed in 500 mM glycine (three times) and fresh OR-2 (three times). Equal numbers of intact oocytes from each experimental condition were selected and transferred to microcentrifuge tubes and homogenized by gentle trituration in lysis buffer, LyB (10 μl per oocyte; 2% Nonidet P-40, 150 mM NaCl, 2 mM CaCl₂, 20 mM Tris-HCl, pH 7.4, plus 1 protease inhibitor cocktail tablet [Roche Applied Science] into 10 ml of lysis buffer before use). The homogenate was centrifuged twice (1,000 g, 10 min, 4°C) to remove the yolk platelets. The supernatant was sonicated (2 min), centrifuged (1,000 g, 10 min, 4°C), and dialyzed overnight at 4°C against streptavidin buffer (SAv buffer: 0.3% Nonidet P-40, 500 mM NaCl, 1 mM CaCl₂, 1 mM MgCl₂, 10 mM Tris-HCl, pH 8) in Slide-A-Lyzer Dialysis Cassettes (3.5K MWCO, Pierce Chemical Co.). The homogenate was centrifuged (1,000 g, 10 min, 4°C) and biotinylated proteins were isolated using streptavidin-agarose beads (Thermo Scientific). Beads were recovered by centrifugation (853 g), washed in SAv buffer (three times). Protein was eluted by boiling beads in Laemmli buffer and 2-mercaptoethanol for 2 min. Proteins were separated by SDS-PAGE (100–130 oocyte equivalents per lane). Myc-tagged MEC-4d was detected in Western blots using an HRP-conjugated c-Myc antibody (9E10, Santa Cruz Biotechnology, 1:500 dilution in PBS-T [137 mM NaCl, 2.7 mM KCl, 10 mM Na₂HPO₄, 1.8 mM KH₂PO₄, 0.1% Tween-20] with 5% nonfat dry milk). HRP was detected using chemiluminescence (ECL plus, GE Life Sciences) and blots were visualized with a CCD-based luminometer (Fluorchem 8800 with Multimage light chamber chemiluminescent filter, Alpha Innotech). Digital images were used to determine the relative amounts of protein by densitometry in ImageJ (NIH).

**MEC-2 Expression**

10 intact oocytes were selected 4 d after cRNA injection and homogenized by gentle trituration in LyB with protease inhibitor (see above). The homogenate was centrifuged (1,000 g, 10 min, 4°C) and separated by SDS-PAGE (two oocyte equivalents per lane). MEC-2 was detected by Western blotting with anti-MEC-2 rabbit primary (Zhang et al., 2004a) and HRP-conjugated secondary (Santa Cruz Biotechnology), blocked, washed and visualized with the same reagents as for MEC-4 Western blots (above).

**Cholesterol Depletion**

Immediately after injection, oocytes were divided into two groups. The control group was incubated in L-15 supplemented with gentamicin (144 μM) and amiloride (300 μM). The experimental group was also treated with methyl-β-cyclodextrin (5 mM) and pravastatin (250 μM). Amiloride-sensitive currents were measured 4–6 d later. Between 5 and 17 oocytes in each group were tested.

**Reagents**

Except as noted above, chemicals were obtained from Sigma-Aldrich. Amiloride was diluted from 0.1 M stock solutions in DMSO.
RESULTS

To measure the effects of MEC-2 and MEC-6 on open probability ($P_o$), single channel conductance ($\gamma$), and open- and closed-state dwell times, we excised outside-out patches from *Xenopus* oocytes injected with the cRNA encoding MEC-4d/10d alone, with MEC-2, with MEC-6, and with both MEC-2 and MEC-6. In A–D, two sections are shown: the left demonstrates the sensitivity of the channel to amiloride (50 $\mu$M), while the right shows the channel behavior in control saline. $V_{\text{hold}} = -150$ mV. Closed and open states are labeled C and O respectively and indicated by solid lines. To the right of each record is an all-points histogram of the same trace; dotted lines represent Gaussian fits to each peak. Open probability (E) and single-channel conductance (F) of patches containing a single channel. Data are summarized in Table 1. Closed triangles represent the example patches shown in A–D. Bars indicate mean values for each isoform. Number of patches indicated in parentheses.

* $,$ significantly different from MEC-4d/10d ($P < 0.01$).

Figure 1. Single-channel recordings from outside-out patches. (A) MEC-4d/10d only. (B) MEC-4d/10d + MEC-2. (C) MEC-4d/10d + MEC-6. (D) MEC-4d/10d + MEC-2 + MEC-6. In A–D, two sections are shown: the left demonstrates the sensitivity of the channel to amiloride (50 $\mu$M), while the right shows the channel behavior in control saline. $V_{\text{hold}} = -150$ mV. Closed and open states are labeled C and O respectively and indicated by solid lines. To the right of each record is an all-points histogram of the same trace; dotted lines represent Gaussian fits to each peak. Open probability (E) and single-channel conductance (F) of patches containing a single channel. Data are summarized in Table 1. Closed triangles represent the example patches shown in A–D. Bars indicate mean values for each isoform. Number of patches indicated in parentheses.

*, significantly different from MEC-4d/10d ($P < 0.01$).

Statistics and Curve Fitting

Curve fitting was performed with nonlinear least-squares regression in Igor Pro (Wavemetrics). Statistical comparisons were performed as Student’s t test assuming unequal variances and analysis of variance (ANOVA). ANOVA results are expressed as $F(a,b) = c$, $P = d$ where $a$ and $b$ are the degrees of freedom between and within groups, $c$ is the $F$ value, and $d$ is the probability in insignificance.

Dwell-Time Analysis

Open and closed channel dwell times were generated from single-channel idealizations determined using QuB. All single-channel patches were used to generate average dwell times, $T_{\text{open}}$ and $T_{\text{closed}}$; only patches with more than 1,000 events were used to generate histograms of dwell times. Dwell times were converted into histograms with logarithmic bins and plotted with a square-root ordinate and fit with a sum of exponentials, as previously described (Sigworth and Sine, 1987). At small dwell times, some bins contain no even multiple of the sampling interval and are empty as an artifact of logarithmic binning. To lessen this effect for display purposes, histograms were smoothed across adjacent bins.

Online Supplemental Material

The online supplemental material (Figs. S1 and S2) is available at http://www.jgp.org/cgi/content/full/jgp.200709910/DC1). Fig. S1 compares dose-response curves for blockade by amiloride in the presence and absence of divalent cations. Fig. S2 shows the surface expression of myc-tagged MEC-4d channels in the presence and absence of MEC-2 and MEC-6.

Neither MEC-2 nor MEC-6 Affects Average $P_o$ nor Dwell Times in the Open or Closed State

Single channels of the four heteromeric channel complexes studied in this report exhibited similar characteristics...
to one another (Fig. 1), including subconductance states similar to those reported previously for homomeric MEC-4 channels (Brown et al., 2007). While we observed a range of $P_o$ values for each channel complex, average values for $P_o$ showed no significant dependence on the presence or absence of MEC-2, MEC-6, or both proteins (Fig. 1E and Table I).

We also examined channel kinetics and performed dwell-time analyses. We did not observe any MEC-2–or MEC-6–dependent changes in the average open- or closed-state lifetimes (Tables II and III). Regardless of the channel isoform being studied, all single-channel dwell-time histograms demonstrated the existence of multiple closed and open states. Fig. 2 shows dwell-time histograms of open and closed times for a sample patch containing MEC-4d/10d + MEC-2 + MEC-6. Most (8/12) patches required three open and three closed states to generate satisfactory fits. The remaining four patches required either only two open or two closed states to generate an adequate fit. In each case, fit quality was examined by measuring sum-squared error (SSE) as a function of the number of states. Generally, SSE decreased significantly upon addition of a second and a third state, but was insensitive to the addition of a fourth, fifth, or sixth state (unpublished data). Similar to average lifetimes, dwell times of individual states extracted from fits to histograms do not demonstrate any significant dependence on the presence or absence of auxiliary subunits (Tables II and III). MEC-2, but not MEC-6 Increases Single Channel Conductance

We did observe one significant effect on single channel properties; with MEC-2 present, the single-channel conductance of the larger subconductance state ($\gamma_2$) is increased by 30% ($P < 10^{-5}$) (Fig. 1 and Table I). While robust and reproducible, this difference in $\gamma_2$ would account for only ~1% of the observed ~40-fold increase in whole-cell current (Goodman et al., 2002a) and $NP_o$ (see below) produced by MEC-2.

MEC-2 and MEC-6 Increase $NP_o$

Based on these findings, we predicted that MEC-2 and MEC-6 would enhance $NP_o$ in multichannel patches. Since $N$ is the number of active channels in the patch (rather than the total number of proteins), such an effect is compatible with biochemical evidence showing that neither MEC-2 nor MEC-6 increase surface expression of MEC-4 or MEC-10 (see Chelur et al., 2002; Goodman et al., 2002a; and Fig. S2). Membrane patches from cells co.injected with 5–10 ng of cRNA encoding MEC-4d and MEC-10d rarely contained more than one channel. Thus, in the absence of MEC-2 and MEC-6, $NP_o$ is <1. Consistent with our prediction, co-injecting MEC-2 increases $NP_o$ to 33 ± 6 (n = 6), co-injecting MEC-6 gives $NP_o = 61 ± 24$ (n = 7), and co-injecting both auxiliary subunits gives $NP_o = 718 ± 202$ (n = 10). Thus, co-injecting MEC-2 and MEC-6 cRNA increases current to an even greater extent than predicted from whole-cell reports (200–400-fold) (Chelur et al., 2002; Goodman et al., 2002a).

Calcium Blocks and Permeates Heteromeric MEC-4d/10d Channels

In initial single-channel recordings, we observed only brief openings suggestive of fast, flickering blockade (unpublished data), which was reduced when divalent cations were removed from recording solutions. To test if this block was indeed due to Ca$^{2+}$ and Mg$^{2+}$ ions, we systematically varied the concentration of divalent ions.

Average closed-time, $<t_1>$, ANOVA: $F(3,22) = 0.59$, $P = 0.63$
MEC-2 and MEC-6 Enable DEG/ENaC Channel Activity and 2 mM Mg$^{2+}$ (Fig. S1, available at http://www.jgp.org/cgi/content/full/jgp.200709910/DC1).

We also examined whether MEC-2 or MEC-6 alter block by Ca$^{2+}$. Both MEC-2 and MEC-6 decrease the apparent affinity for Ca$^{2+}$ ions (Fig. 3). If Ca$^{2+}$ is a permeant blocker, then increasing external [Ca$^{2+}$] should shift the reversal potential to more positive potentials. Consistent with this idea and with prior work demonstrating that MEC-4 channels are Ca$^{2+}$ permeable (Bianchi et al., 2004), currents recorded in 10 mM Ca$^{2+}$ reversed +1.8 ± 0.2 mV (n = 5) more positive than those recorded in nominally 0 mM Ca$^{2+}$. This small shift is consistent with $\Delta E_{rev}$ estimated using the Goldman-Hodgkin-Katz current (see Lewis, 1984), assuming the measured Ca$^{2+}$ permeability $P_{Ca}/P_{Na}$ = 0.22 (Bianchi et al., 2004). Channels containing only MEC-4d/10d were not analyzed since patches contained too few channels for analysis.

Protease Activates MEC-4-dependent Channels Independently of MEC-2 and MEC-6

Both native and expressed ENaCs can be activated by proteases (Planes and Caughey, 2007). It is not known whether proteases can also activate MEC-4/10 channels. We investigated this by applying chymotrypsin, a serine protease known to activate ENaCs (Chraibi et al., 1998), to MEC-4d/10d channels expressed in oocytes. As shown in Fig. 4, chymotrypsin application increases amiloride-sensitive currents in whole oocytes. The slight shift of reversal potential toward zero is likely due to sodium loading of the cell, and is observed on similar timescales when no protease is applied (unpublished data). Chymotrypsin increased current by approximately two-fold in the presence and absence of MEC-2 and MEC-6, indicating that neither auxiliary protein affects sensitivity to proteases. These data indicate that the mechanisms by which protease and MEC-2/MEC-6 increase current are distinct.

MEC-2 and MEC-6 Promote Channel Activity without Increasing Surface Expression

By contrast with their dramatic effects on whole-cell current (Chelur et al., 2002; Goodman et al., 2002a), MEC-2 and MEC-6 have only modest effects on single-channel currents (Table I, Fig. 1, Table II, and Table III). We considered two possible explanations. First, auxiliary proteins could increase the total number of channels at

![Figure 2. Example dwell-time histograms of single channel recordings. (A) Dwell-time histogram of the closed states of a single MEC-4d/10d + MEC-2 + MEC-6 channel. (B) Dwell-time histogram of the open states of the same channel as in A. For optimal visual estimation of fit quality (Sigworth and Sine, 1987), dwell times are accumulated into logarithmic bins and displayed with a square-root ordinate. Solid lines are fits to the data with the sum of three exponential functions, dotted lines represent each exponential component.]

| Table III | Open-State Dwell Times of Single MEC-4d/10d Channels and Effects of Auxiliary Subunits |
|-----------|----------------------------------------------------------------------------------------|
|           | $\tau_1$  | $P_{o1}$ | $\tau_2$ | $P_{o2}$ | $\tau_3$ | $P_{o3}$ |
| MEC-4d/10d | 250 ± 60 (11) | 0.26 (3) | 2.2 (2) | 0.40 (3) | 37 (3) | 0.33 (3) | 180 (3) |
| +MEC-2     | 340 ± 210 (7) | 0.29 (3) | 1.7 (3) | 0.29 (3) | 13 (3) | 0.43 (3) | 110 (3) |
| +MEC-6     | 490 ± 140 (4) | 0.29 (2) | 7.9 (2) | 0.40 (2) | 79 (2) | 0.31 (2) | 1200 (2) |
| +MEC-2 +MEC-6 | 240 ± 84 (5) | 0.38 (4) | 1.8 (4) | 0.17 (3) | 14 (4) | 0.45 (4) | 500 (4) |

610 MEC-2 and MEC-6 Enable DEG/ENaC Channel Activity
the oocyte membrane. Prior work showing that neither MEC-2 (Goodman et al., 2002a) nor MEC-6 (Chelur et al., 2002) increases surface expression makes this explanation unlikely, however. Nonetheless, it is formally possible that surface expression increases when both MEC-2 and MEC-6 are present. We tested this idea by comparing the amount of myc-tagged MEC-4d expressed in the plasma membrane in the presence and absence of both MEC-2 and MEC-6. We found that addition of MEC-2 and MEC-6 did not produce a detectable change in the amount of myc-tagged MEC-4d protein in the plasma membrane (Fig. S2).

Second, the auxiliary proteins could act by increasing the fraction of active membrane-inserted channels. That is, in the absence of these subunits, active channels are rare, but exhibit properties similar to those bound to MEC-2 and MEC-6. To demonstrate this directly, we injected varying amounts of cRNA encoding MEC-2 along with constant amounts of cRNA encoding MEC-4d/10d and MEC-6. We measured current and surface protein levels in parallel and found that while surface protein level does not change detectably, current increases with the amount of MEC-2 cRNA (Fig. 5). Since MEC-2 cannot form channels by itself (Goodman et al., 2002a), has a modest effect on single-channel conductance, and has no effect on steady-state open probability, this finding demonstrates that increasing the amount of MEC-2 enhances current by increasing the fraction of membrane-inserted MEC-4d protein that carries current.

MEC-2 Palmitoylation and Cholesterol-binding Activity Are Required for Channel Activation

We also interrogated the mechanism by which MEC-2 activates channels. Specifically, we tested which aspects of MEC-2 function were required for its current-enhancing effect. As shown in Fig. 6, we targeted three residues involved in cholesterol binding: P134, C140, and C174. Replacing the wild-type cysteine with alanine at amino acids 140 and 174 eliminates palmitoylation and reduces cholesterol binding (Huber et al., 2006). Replacing the proline at 134 with serine recapitulates the mec-2(u274) allele, which causes touch insensitivity in vivo (Zhang et al., 2004a) and abolishes cholesterol binding in vitro (Huber et al., 2006). We found that coinjection of the palmitoylation mutant MEC-2(C140/174A) produces currents larger than those in the absence of MEC-2, but smaller than those recorded with wild-type MEC-2. Coinjection of MEC-2(P134S) produces none of the current enhancement provided by wild-type MEC-2 (Fig. 6); amiloride-sensitive currents were indistinguishable from those recorded in the absence of MEC-2. Currents produced by the triple mutant MEC-2(P134S, C140/174A) were indistinguishable from those produced by single mutant MEC-2(P134S) (Fig. 6).
Since MEC-2 increases single-channel conductance, we also examined if the mutant form of MEC-2 retained the ability to increase γ. In six patches excised from oocytes expressing MEC-4d/10d + MEC-2(P134S, C140/174A) + MEC-6, the single channel conductance was similar to that of channels lacking MEC-2, and significantly different from channels with wild-type MEC-2 (P < 0.01). These data emphasize the importance of cholesterol binding for the modification of channel biophysics by MEC-2.

The inability of MEC-2 isoforms containing the P134S mutation to enhance macroscopic current cannot be explained by a lack of protein, since mutant MEC-2 isoforms were readily detected in whole-cell lysates. (Fig. 6). As shown previously (Huber et al., 2006), wild-type MEC-2 appeared as a doublet near the predicted molecular weight. The P134S mutation altered the relative intensity of the two bands. Though the molecular basis for this observation is unclear, one appealing possibility is that cholesterol-modified MEC-2 is the dominant...
the MEC-2 and MEC-4 sensory mechanotransduction channels both in heterologous cells and in vivo. Consistent with this model, MEC-2 is required for force-dependent gating in vivo (O’Hagan et al., 2005). The in vivo role of MEC-6 is more complex, since it is also required for channel localization (Chelur et al., 2002).

This study also demonstrates the existence of multiple closed and open states in constitutively active channels. How these states might be involved in the regulation and activity of the channel is not yet clear, but the analysis does reveal a complexity of gating. Except for a MEC-2–dependent 30% increase in $I/V_{9253}$, MEC-4d/10d channel behavior is qualitatively and quantitatively similar in the absence or presence of MEC-2, MEC-6, or both MEC-2 and MEC-6.

**Divalent and the MEC-4 Sensory Transduction Channel**

We have shown that the divalent ions Ca$^{2+}$ and Mg$^{2+}$ block channels formed by the MEC-4 complex in a voltage-dependent manner. A voltage-dependent block of similar affinity has been reported in certain mutant versions of ENaC (Schild et al., 1997) and in the related acid-sensing ion channels (ASICs) (Waldmann et al., 1997; de Weille and Bassilana, 2001).

One interesting consequence of block by divalent ions is that a significant fraction of current in whole-cell...
recordings has likely been blocked by divalents in control recording solutions. Also, due to the difference in divalent affinity between channels with and without MEC-2 and MEC-6 (Fig. 3), a larger fraction of current would be blocked in cells lacking MEC-2 and MEC-6. This would have led to an underestimate of current in these cells and accounts for some fraction of the increase in macroscopic current ascribed to MEC-2 and MEC-6. If this difference in affinity for block by divalent ions was the only effect of MEC-2 and MEC-6, coexpression of the auxiliary subunits would increase current by 50%. As this maneuver increases current by ~100-fold (Chelur et al., 2002), a difference in divalent block only accounts for a small fraction of the effect of auxiliary subunits.

**The Role of MEC-10 in the Complex**

Several lines of evidence point to MEC-10 as an inhibitory unit of the sensory transduction channel. First, MEC-10–induced neurodegeneration is a weaker phenotype that can be suppressed by many alleles of other mec genes (Huang and Chalfie, 1994). Second, while MEC-10 is not required for MEC-4 channel activity in oocytes, coexpressing MEC-10 decreases macroscopic current (Goodman et al., 2002a). However, the effect of MEC-10 on single-channel properties seems to be small or nonexistent. Comparing our present results for channels composed of MEC-4d/10d and MEC-2 to values previously reported for channels composed only of MEC-4d and MEC-2, we find $\gamma_2$ (38.3 pS vs. 38.0 pS) and $P_o$ (0.79 vs. 0.86) to be very similar. Taken together, these results indicate that MEC-10 may regulate the MEC-4 channel complex activity by a similar mechanism to that proposed for MEC-2 and MEC-6, that is, by controlling the number of channels accessible for activation. However, the synergistic current enhancement given by MEC-2 and MEC-6 is largely independent of the presence of MEC-10 (Goodman et al., 2002a; Chelur et al., 2002), suggesting that these effects work in parallel.

**The Interaction between MEC-2 and the Channel Pore**

MEC-2, which cannot form channels on its own and is associated only with the inner leaflet of the plasma membrane, modifies the MEC-4 channel pore. Two lines of evidence support this conclusion. First, MEC-2 decreases the affinity of the MEC-4 channel for two open channel blockers: amiloride (Chelur et al., 2002) and divalent ions (this study). Second, MEC-2 significantly increases single-channel conductance. These effects could reflect a long-range conformational change in the channel pore produced by MEC-2, cholesterol binding, or both. Alternatively, they could indicate that MEC-2 directly modifies the inner vestibule of the channel. Additional studies will be required to distinguish among these possibilities. One region of MEC-2 that could affect the inner vestibule and account for the ability of MEC-2 to increase single channel conductance is a stretch of negatively charged amino acids (297–314) that could potentially concentrate Na’ ions near the pore. In support of this idea, three glutamate residues (E297, E299, and E314) are mutated to lysine in three mec-2 alleles ($u318$, $e1514$, and $u217$, respectively) that disrupt touch insensitivity in vivo (Zhang et al., 2004a).

**CouldAccessory Proteins Regulate Membrane Environment?**

Membrane environment is intimately tied to channel function, with particular regard to proteins that sense force (Anishkin and Kung, 2005). This is most obvious in channels that can be activated by membrane stretch alone, such as MscL and MscS, but could be equally important in the activation of channels by force delivered through other modalities. Several recent models propose methods to couple membrane properties such as curvature, thickness, and fluidity to force activation (Markin and Sachs, 2004; Moe and Blount, 2005). The cocrystallization of head groups of detergent molecules in the recent ASIC1 structure (Jasti et al., 2007) provides evidence that hydrophobic molecules, including lipids, may also bind channels directly.

An appealing possibility is raised by the cholesterol and fatty acid binding properties of MEC-2 and the importance of these properties for function. MEC-2 can easily be conceived as having a strong role in regulating the membrane environment of the channel, either by localizing the complex to regions of high cholesterol or by directly recruiting cholesterol to the area of the membrane surrounding the channel. This hypothesis is supported by the observation that MEC-2 oligomerizes (Zhang et al., 2004a; Huber et al., 2006) and our finding that MEC-2 enhances channel activity in a dose-dependent manner. MEC-2 may alter membrane environment as a function of the quantity of protein present by increasing cholesterol concentration proportionately. This could be a consequence of cholesterol’s putative role in local thickening and stiffening of the bilayer and shifting the lateral pressure profile (Cantor, 1999; Gandhavadi et al., 2002; Niemela et al., 2007).

The membrane environment is potentially a unifying mechanism for the roles of MEC-2 and MEC-6. While nothing is known about the affinity of MEC-6 for cholesterol or other membrane components, paraoxonases are known to be associated with HDL particles (Draganov et al., 2000) and PON1 has one nontransmembrane helix proposed to mediate lipid interaction via aromatic amino acids (Harel et al., 2004). This helix is likely present in MEC-6, and several of the highlighted aromatic amino acids are conserved; we propose that this helix may enhance lipid association in MEC-6 as well. While it remains highly speculative, the modes of action and
synergism of MEC-2 and MEC-6 could be explained if each regulates the membrane environment on its respective leaflet of the bilayer, MEC-2 on the intracellular and MEC-6 on the extracellular side. Thus, the membrane environment is likely to be a critical parameter of channel activity and, possibly, of force-dependent gating in vivo.

We thank G. Martinez and B. Johnson for suggestions regarding the manuscript.
