INTRODUCTION

Primary duodenal adenocarcinoma (PDA) is a rare gastrointestinal malignancy, reportedly accounting for 0.3% of all cancers involving the alimentary tract (1,2). In addition to its low incidence, PDA is generally investigated and grouped with jejunal/ileal adenocarcinoma (3). Detailed information specifically regarding...
Factors Impacting Survival Outcomes after Curative Resection for Primary Duodenal Adenocarcinoma

PDA-associated factors is hence limited. Complete surgical extirpation, when feasible, has long been deemed the optimal curative approach for PDA, with the possibility of achieving long-term postoperative survival. However, the best care during the perioperative term has yet to be established. In the present study, we assessed the clinical significance of key prognostic indicators with the aim of developing novel therapeutic strategies.

We retrospectively investigated clinicopathological characteristics of patients undergoing surgical resection with curative intent (R0) for PDA to identify which factors showed meaningful correlations with survival outcomes.

PATIENTS AND METHODS

Study population

We identified, from a database prospectively stored by the Department of Gastroenterological Surgery, Toranomon Hospital, 45 consecutive patients who had undergone surgery for PDA between July 1988 and September 2019. Those undergoing resection of carcinoma arising in the papilla of Vater (n = 3), surgical palliation (gastrojejunostomy bypass) (n = 5), R1/R2 resection (n = 2), emergency operations (n = 1) and/or with follow-up periods of less than four months (n = 1) were excluded from the analysis.

The remaining 33 cases were retrospectively reviewed and included in this investigation. All analyses carried out in the current study were in accordance with the ethical guidelines established by Toranomon Hospital. Informed consent from the patients was not necessary due to the retrospective design of this study.

Clinicopathological data

We thoroughly reviewed the subjects’ medical records to obtain relevant clinical data. The necessary histological parameters, i.e. tumor location, histological grade, depth of tumor invasion, nodal metastasis, and lymphovascular involvement, were available for all subjects.

Preoperative examinations for elective abdominal surgery consist mainly of physical assessment, laboratory testing, esophagogastroduodenoscopy, endoscopic ultrasound, contrast-enhanced computed tomography, and, if necessary, positron-emission tomography with 18 F-Fluorodeoxyglucose. The serum carcinoembryonic antigen (CEA) level had been measured within 30 days prior to surgery in all subjects. Preoperative blood hemoglobin, serum albumin and serum C-reactive protein levels were determined during the week before surgery. Cut-off values for each index used in the survival analyses were based on our institutional standards.

Routine postoperative surveillance included physical examination and blood testing at every visit. Esophagogastroduodenoscopy and contrast-enhanced computed tomography were also performed every 6 or 12 months, for up to 5 years postoperatively.

Postoperative complications were defined as those of grade II or greater severity, according to the Clavien-Dindo classification (4).

Statistical analysis

The Kaplan-Meier method was used to create survival curves. The log-rank test was applied to analyze differences between the curves. We calculated univariate and multivariate hazard ratios using the Cox proportional hazard model. Variables with P < 0.1 in the univariate analysis were included in the multivariate analysis. Overall survival (OS) calculations were from the date of surgery to the date of death from any cause, with censoring at the time of the last follow-up. Relapse-free survival (RFS) was calculated from the date of surgery to the date of recurrence or death, regardless of cause, with censoring at the time of the last follow-up.

Values of P < 0.05 (two-tailed) were considered significant for all analyses. All of the statistical analyses were carried out employing JMP Pro 14.2.0. (SAS Institute, Cary, NC).

RESULTS

Patient and tumor characteristics

The demographic variables of all 33 subjects are summarized in table 1. There were 23 men and 10 women, with a median age of 68 (50-86) years. The most frequent tumor location was the second portion of the duodenum (20/33, 60.6%). Tumor invasion was limited to the mucosal/submucosal layer in the majority of patients (19/33, 57.6%), while pancreatic invasion across the serosa was pathologically confirmed in six (18.2%). Lymph node metastasis was documented in six patients (18.2%), of whom three had multiple nodal metastases (9.1%). Lymphovascular involvement was present in 18 patients (54.5%). Seven (21.2%), ten (30.3%) and 16 (48.5%) patients had undergone gastrectomies, partial duodenectomies and pancreato-duodenectomies, respectively. Only four cases (12.1%) had been given adjuvant chemotherapy, oral
tegafur-uracil in accordance with the results of randomized controlled trial for treatment of colorectal carcinoma (5): one with tumor invasion of the submucosa accompanied by a single nodal metastasis and three with pancreas-invading tumors but no metastasis to regional lymph nodes.

After a median follow-up period of 44.5 (4.4-193.3) months, nine patients (27.3%) experienced disease recurrence and there were 13 deaths (39.4%), from various causes. There were no mortalities during the 30-day period after surgery. Kaplan-Meier analyses for OS and RFS focused on the following tumor factors: location, histological grade, tumor size, depth of invasion, nodal metastasis, and lymphovascular involvement.

Trichotomous analysis for tumor invasion depth yielded overall P values far below the level of significance (OS P = 0.005, RFS P < 0.001) (figure 1a). Notably, while patients with pancreatic invasion showed clearly unfavorable outcomes as compared to those free of such invasion, the differences between the survival curves of the other two groups did not reach statistical significance (mucosa-submucosa vs. muscularis propria-serosa, OS P = 0.99, RFS P = 0.68).

The analysis focused on nodal metastasis demonstrated that survival outcomes were significantly poorer when the tumor had metastasized to multiple lymph nodes (≥ 2) (OS P = 0.002, RFS P < 0.001) (figure 1b).

Other factors, including tumor location (part 1 vs. 2 vs. 3), histological grade (well-moderately differentiated vs. poorly-undifferentiated), size (≤ 30 mm vs > 30 mm) and lymphovascular involvement (absent vs. present), showed no significant associations with OS/RFS based on the Kaplan-Meier estimations (supplemental figure S1).

To identify survival predictors in PDA patients, the cumulative OS/RFS rates were compared for 18 clinicopathological factors in total (table 2). In univariate Cox regression analysis, depth of invasion (pancreatic invasion) was found to be significantly associated with both OS (hazard ratio [HR] 7.27, 95% confidence interval [CI] 1.86-28.5, P = 0.004) and RFS (HR 27.2, 95% CI 5.30-139, P < 0.001). Nodal metastasis (more than one) also showed a statistically significant relationship with OS (HR 19.9, 95% CI 1.79-
Figure 1 - Kaplan-Meier curves of overall survival (OS) and relapse-free survival (RFS) stratified according to (a) tumor invasion depth and (b) lymph node metastasis. M mucosa, SM submucosa, MP muscularis propria, SE serosa

RFS, pancreatic invasion and multiple nodal metastases remained independent factors (HR 42.8, 95% CI 3.59-510, P = 0.003; HR 216, 95% CI 6.86-6.8 × 10^3, P = 0.002; respectively).

Pattern of recurrence

Nine of our subjects had developed disease recurrence: five peritoneal metastases, two hepatic...

metastases, one lymph node metastasis and one local site relapse (fig. 2). It is noteworthy that recurrent disease (local site) was reported in only one of the 19 patients with mucosa/submucosa-invading PDA (1/19, 5.3%), while all six with pancreatic invasion experienced distant recurrence (five peritoneal and one hepatic) (6/6, 100%) and five died of their disease. Similarly, all three patients with multiple nodal metastases (two with pancreatic invasion) developed metachronous disease (two peritoneal and one nodal) (3/3, 100%).

**DISCUSSION**

We assessed clinicopathological factors possibly influencing the outcomes of patients undergoing R0 resection of PDA. This retrospective study revealed pancreatic invasion and multiple lymph node metastases to be independent predictors of poorer survival outcomes. Of note, all of the patients with pancreatic invasion and/or multiple nodal metastases (n = 7) ultimately developed distant metachronous recurrence. This observation suggests PDA to possibly be in the systemic phase characterized by invasion of the pancreas and/or metastasis to multiple lymph nodes. Thus, in such a population, perioperative systemic therapy in addition to conventional surgical resection might well be warranted.

Regarding therapeutic strategies, controversy persists as to how to improve the clinical outcomes of high-risk populations susceptible to recurrent disease. Despite previously reported contradictory results (6,7), recent lines of retrospective evidence have
suggested that adjuvant chemotherapy, mainly regimens employing oxaliplatin with either infusional 5-fluorouracil or capecitabine, may provide survival benefits for patients with lymph node-positive PDA (8–10). Furthermore, a large-scale randomized controlled trial (ESPAC-3) showed adjuvant chemotherapy (fluorouracil plus folinic acid or gemcitabine) to yield a significant survival benefit, although results specific to PDA were limited (11). Adjuvant chemoradiation reportedly improved locoregional control after surgery for PDA in some studies (12–15), while another group documented adjuvant chemoradiation to neither decrease local recurrence nor prolong overall survival (16). The role of preoperative chemotherapy remains to be determined, as this approach is supported by no more than a few case series (17–19). As yet, we have no standardized evidence supporting the concept of perioperative chemotherapy/chemoradiotherapy prolonging OS in patients with PDA. To improve the survivals of patients with advanced PDA, additional prospective evidence relating to the role of systemic therapy is eagerly awaited.

Our results also raise the possibility of there being little risk of PDA relapsing systemically when the primary tumor is limited to the mucosal/submucosal layer and is therefore deemed potentially curable, assuming complete surgical R0 resection. To fully extirpate an early-stage PDA, pancreatectoduodenectomy is frequently required to achieve complete tumor removal because this tumor frequently originates in the second portion of the duodenum adjacent to the pancreas (17,20,21). Pancreatectoduodenectomy is both highly invasive and complex, carrying a high mortality/morbidity rate (reported hospital mortality 1.7%)(21-23). The indications for pancreatectoduodenectomy as a procedure for treating PDA thus remain controversial (24-28). In the current study, the 16 pancreatectoduodenectomies performed were not associated with short-term mortality and the survival rate was comparable to that of a cohort undergoing other procedures (table 2). However, the rate of postoperative complications (mainly delayed gastric emptying) was significantly higher than in the non-pancreatectoduodenectomy group (13/16 vs. 8/17, P = 0.041, by the chi-squared test). Pancreatectoduodenectomy is acceptable if it is the only surgical intervention allowing complete tumor removal. If other options are available, however, the indications for pancreatectoduodenectomy should be carefully considered.

As to non-tumor factors, only the preoperative CEA level (> 5 ng/mL) was significantly associated with RFS in our univariate analysis, but this factor lost independence in the multivariate analysis (table 2). Though the prognostic significance of the CEA level is widely accepted and this factor is routinely measured preoperatively in colon cancer cases (29), its predictive value in PDA remains uncertain.

Limitations of the present study include its retrospective nature and the relatively small number of subjects. However, surgical managements were highly consistent during the study period because the operations had all been performed by the same surgical team at our tertiary institution. Also, the current study is based on a prospectively collected database registering consecutive patients with follow-up of sufficient duration. Although further validation with a larger sample size is needed before definite conclusions can be drawn, we hope that our observations will contribute to establishing optimal therapeutic strategies for operable PDA.

CONCLUSION

We aimed to retrospectively identify key survival factors in patients who had received curative resection of PDA. Patients with PDA limited to the mucosa/submucosa rarely showed progression to systemic disease. Meticulous operative approaches, despite being highly invasive, may provide curative treatment for such PDA patients. On the other hand, patients with unfavorable
tumor features, such as pancreatic invasion and/or multiple lymph node metastases, were highly likely to develop distant relapse even after R0 extirpation of the tumor and may benefit from additional systemic therapy.

Ethical approval

This study was approved by the ethics committee of Toranomon Hospital. All procedures performed in studies involving human participants were in accordance with the ethical standards of the institutional and/or national research committee and with the 1964 Helsinki Declaration and its later amendments or comparable ethical standards.
