ABSTRACT

In the field of photocatalysis, the heterojunction strategy is one of the effective ways to settle the problems of rapid recombination and sluggish mobility of the photo-generated carriers. Herein, we used a strategy of electrophoretic deposition to synthesize Z-scheme CdS/BiVO₄. Interestingly, compared with the pristine CdS and BiVO₄, the prepared CdS/BiVO₄ showed effective charge separation, high degradation efficiency and well photocatalytic stability. It demonstrated that electrophoretic deposition can successfully construct photocatalyst steadily and effectively heterostructured CdS/BiVO₄. Meanwhile, the electron transfer paths between BiVO₄ and CdS were probed by the DFT calculations. We infer that there is a Z-scheme mechanism between BiVO₄ and CdS. Moreover, this efficient strategy can support more efficient composition design of semiconductor heterojunctions.

1. Introduction

Environmental pollution and energy crisis have brought about considerable attentions to the researchers in recent years. Photocatalysis provides a feasible strategy for alleviating above issues due to potential applications in degrading organic pollutants and photocatalytic water splitting [1-4]. However, the wide band gap, the rapid recombination of the photo-generated carriers and fewer surface active sites result in that the photocatalytic abilities of semiconductor photocatalysts were limited [5-8]. Consequently, to obtain the efficient and stable photocatalysts, the rationalized regulating strategy is crucial.

Up to now, various regulating strategies have been reported various strategies such as doping [9-11], surface modification [12,13], construction of heterostructure [14-16] and homojunction [17] etc. Among the methods mentioned above, the construction of heterojunction will lead to the alignment of the Fermi level of the semiconductor photocatalysts and thereby generate the interfacial electric field, which would effectively facilitate the separation of photo-generated carriers [18]. And the direct Z-scheme heterostructure is ascribed to the reduction and oxidation potential of the photocatalyst be optimized and the promotion of the spatial transfer of photo-generated carriers, and become a hot topic in the field of heterojunction [19]. Despite composite photocatalysts have revealed many advantages, most approaches in preparing composite photocatalysts exist some limitations to some extent. P. Joice Sophia et al. synthesized CdS/Ag₂O nanocomposites by chemical precipitation method [20]. In this method, the excessive NaOH was added in the preparation process to generate Ag₂O, which will lead to multiple subsequent cleaning, and the generated flocculent precipitation needed to be dried at 160 °C. He et al. synthesized BiOCl/BiVO₄ heterostructures through a hydrothermal process of keeping at 180 °C for 10 h and drying at 80 °C for 10 h [21]. A long crystal phase growth time of multicomponent coexistence may bring
about the impurity and high product cost. Also more uncontrollable factors and high cost in the process of utilizing traditional methods to synthesize the composite photocatalyst are not suitable for the industrial production [22].

In recent years, numerous works have been concentrated on CdS and BiVO₄ because of their suitable band gap and immense potential application in photocatalysis [23,24]. As a type II-VI direct band gap semiconductor, CdS has been widely employed in light harvesting and photocatalytic experiments due to its suitable valence band position, narrow band gap (about 2.40 eV) and high extinction coefficient [25-27]. When the wavelength of the incident sunlight is less than 495nm, the valence band electrons of CdS are easily excited to enter the conduction band [28,29]. We know, monoclinic scheelite BiVO₄ has revealed superior photocatalytic activities over the other phases because of the narrow band gap (about 2.4 eV) [30,31], low toxicity, abundant sources and well stability [32]. Nevertheless, CdS is more prone to agglomeration during the photocatalysis process, which obviously leads to decrease in surface area and it is difficult to restrain the recombination of photo-generated carriers [33,34]. Consequently, to improve the photocatalytic activity of CdS, it is crucial to seek a convenient and effective approach to form an efficient photocatalyst.

Herein, we proposed a strategy to prepare the photocatalysts of Z-scheme CdS/BiVO₄ with different ratios by controlled electrophoretic deposition method. This physical approach to prepare semiconductor photocatalyst can not only enhance the preparation efficiency and reduce energy consumption, but also there is no need to further purify and dry. The photocatalytic performances of CdS/BiVO₄ were evaluated by photodegradation of rhodamine B (RhB) and methyl orange (MO). Essentially, this physical combining approach is to form electrostatic attraction of interfaces between CdS and BiVO₄, which reasonably construct Z-scheme heterostructure. The transfer mechanism of electrons between BiVO₄ and CdS was investigated by density functional theory (DFT) calculations. We infer that the formation of a Z-scheme heterostructure between BiVO₄ and CdS realizes the interface effect. Thus, the synthesized Z-scheme CdS/BiVO₄ displayed higher efficient photocatalytic activity and stability compared with the pristine CdS and BiVO₄.

2. Experimental Section

2.1 Preparation

All chemicals were reagent grade and used without purification. The traditional hydrothermal method is utilized to prepare BiVO₄ particles: firstly, 2.5 mmol of Bi(NO₃)₃·5H₂O was dissolved in 5 mL of 1 M HNO₃, and magnetically stirred for 30 minutes to obtain a colorless solution A. Then, 2.5 mmol of NH₄VO₃ was dissolved in 2 M NaOH solution, and after magnetic stirring of half hour the clarified solution B was obtained. Subsequently, solution B was added dropwise to solution A to acquire a yellow mixed suspension, and then the pH was adjusted to 7 with 2 M NaOH solution. Ultimately, the mixed suspension was transferred and sealed in a 100 mL Teflon-lined autoclave, heated to 180 °C and maintained for 12 h. The yellow precipitate obtained was collected by centrifugation and washing, and then dried in air at 80 °C.

CdS nanoparticles were prepared by a water bath method. Firstly, 5 mmol sodium citrate was dissolved in 50 mL deionized water, and magnetically stirred for 2 h to obtain a transparent solution. Thereafter, 10 mL of CdCl₂ (0.3 mol L⁻¹) solution was slowly added into the above transparent solution and magnetically stirred for 20 min. Thirdly, 5 mL NH₃·H₂O (28 wt%) and 10 mL 0.9 M thiourea (CH₃N₂S) solution were slowly added into the above mixed solution, respectively. The mixed solution was maintained in a 60 °C water bath for 3 h. The yellow precipitate was collected by centrifugation, then washed thoroughly with ethanol and deionized water, and then dried in the air at 80°C to obtain the product CdS.

CdS/BiVO₄ composites were obtained by depositing pure BiVO₄ and CdS powder samples onto FTO substrate by electrophoretic deposition. In a typical preparation, firstly, 0.05 g CdS, 0.112 g BiVO₄ and 0.005 g I₂ were ultrasonically dispersed in 20 mL acetone according to a molar ratio of CdS and BiVO₄ is 1:1. Secondly, two clean
FTO substrates were attached to the electrodes and inserted into the acetone solution. The conductive surfaces of the two FTO substrates were opposed to each other and kept at a distance of 1 cm. Thirdly, turn on the DC voltage stabilizer and adjust the voltage to 25 V. Under the action of the electric field, the BiVO₄ and CdS were adsorbed on the FTO substrate. Formed uniform film was named as CV-4. The CV-x products with different ratios were prepared according to the molar ratio of CdS to BiVO₄ are 1: 0.25, 1: 0.5, 1: 0.75 (CV-1~CV-3), respectively. Although the proportions of the samples deposited are different, the total mass of the deposits is about 3 mg. Meanwhile, 3 mg of pure BiVO₄ and pure CdS were deposited on their respective FTO by electrophoretic deposition. The mechanism of CdS and BiVO₄ electrophoretic deposition is demonstrated in Figure 1.

![Formation mechanism of electrophoretic deposition of CdS/BiVO₄](image)

**Figure 1.** Formation mechanism of electrophoretic deposition of CdS/BiVO₄

Unlike traditional strategies of composite preparation, our electrophoretic deposition strategy can avoid the growth of the second crystalline phase, which significantly improves the preparation efficiency of high-efficiency photocatalysts [35].

### 2.2 Characterization

The phase structure of the crystalline material of the products was inspected by utilizing X-ray diffraction equipment (Model: X’Pert PRO MPD) with scanning rate of 0.02 s⁻¹ and diffraction angle of 10-70 °. Scanning electron microscope (SEM, FEISirion200) and energy dispersive spectrometer (EDS) were ubiquitously employed to characterize the morphology, grain size and element distribution of the products. The crystal size and structure were investigated by transmission electron microscopy (TEM, JEM2010). The photo-generated carriers recombination rate was detected by fluorescence spectrophotometer (Shimadzu, model RF-5301 PC) at the excitation wavelength of 340 nm. Electrochemical impedance spectroscopy (EIS) and Mott-Schottky spectrum (M-S) were obtained by electrochemical workstation (VMP3). The three-electrode system consists of platinum foil electrode as the counter electrode and saturated calomel electrode as the reference electrode, and 0.5 M Na₂SO₄ as the electrolyte solution.

### 2.3 Photocatalytic experiments

The photocatalytic activities of the obtained products were carried out by degrading MO and RhB under visible light.
light irradiation (300 W Xe lamp). The prepared CdS, BiVO₄, and CV-x (x=1~4) were put into 100 mL of MO (RhB) aqueous solution (10 mg L⁻¹), respectively. In order to ensure the adsorption-desorption equilibrium, the above solutions were placed in the dark for 30 min. Then under visible light irradiation, at a given time interval, we used a UV-Vis spectrophotometer (UV757CRT) to monitor the maximum absorption wavelength (460 nm or 554 nm) for final the photodegradation efficiency. The light absorption of MO at 460 nm (RhB at 554 nm) was monitored for photodegradation process.

2.4 Computational methods and details

To determine the charge transfer between CdS and BiVO₄, we carried out DFT calculations using the Vienna Ab initio Simulation Package (VASP) code [36,37]. Meanwhile, the generalized gradient approximation (GGA) of the Perdew–Burke–Ernzerhof (PBE) is adopted for the exchange and correlation potential [38]. According to previous report, the (010) facet of the C2/c cell with monoclinic lattice constant exhibit approximate band gap, work function, and the lowest surface energy of the (001) facet of the I2/b cell with tetragonal lattice constant [39]. Therefore, we refer to the (001) plane of I2/b cell as the (010) facet. The (010) surface structure of BiVO₄ contains 108 atoms, 8 Bi layers and vacuum slab of 15 Å. It is cleaved from cell with tetragonal lattice parameters (a / b = 5.215 Å, c=11.706 Å, a / β / γ = 90°) of I2/b. Meanwhile, the (100) surface structure of CdS contains 84 atoms, 13 Cd layers and vacuum slab of 15 Å, which is cleaved from cell of P63mc with hexagonal lattice constant. (010) and (100) surface properties are obtained from 6×7×1 and 8×5×1 k-point meshes, respectively.

3. Results and discussion

3.1 Phase structure and composition

The crystalline structures of BiVO₄, CdS and CV-x (x=1~4) were investigated by X-ray diffraction (XRD) as depicted in Figure 2a. The diffraction peak of the pristine CdS and BiVO₄ were detected, which are consistent with the standard CdS (ICSD, no. 41-1049; a / b = 4.141 Å, c = 6.720 Å, a / β = 90°, γ = 120°) and BiVO₄ (space group: I2/a, ICSD, no. 14-0688), demonstrating that the crystal phases of the obtained products was hexagonal phase and monoclinic phase, respectively [40]. In addition, the impurity peaks appeared should belong to the FTO (F doped SnO₂). Figure 2b shows partially enlarged views of 26.5° in Figure 2a. It could be distinctly discovered that the diffraction peak of CdS was continually weakened due to the continuous increase of BiVO₄ content. Hence, the XRD results can illustrate that electrophotoretic deposition can effectively regulate the ratio of composite photocatalysts.

![Figure 2](image-url)

**Figure 2.** The XRD patterns of BiVO₄, CdS, CV-x (x=1~4) and FTO.

3.2 Morphology and microstructure

SEM was employed to investigate the morphology and elemental distribution of CdS, BiVO₄ and CV-3 as portrayed in Figure 3. The microscopic morphology of the as-prepared BiVO₄ was depicted in Figure 3a,
observing irregular worm-like particles with the size of about 1~2 μm [41]. As shown in Figure 3b, the CdS is characteristic of accumulating with numerous tiny nanoparticles. As described in Figure 3c and EDS, all elements (Bi, V, O, Cd, S) were detected in CV-3, corresponding to BiVO₄ and CdS. Meanwhile, the BiVO₄ particles were evenly surrounded by CdS nanoparticles in CV-3. Therefore, it can be inferred that electrophoretic deposition can successfully couple CdS and BiVO₄ to form well-defined microscopic morphology, which is conducive to provide more reactive sites.

**Figure 3.** SEM patterns of sample: (a) BiVO₄; (b) CdS; (c) CV-3 and the corresponding elements mapping.

In order to establish accurate crystal facets model, detailed information about the crystal facets of BiVO₄ and CdS plays a crucial role in heterojunctions. Thus, the synthesized samples (BiVO₄ and CdS) were characterized by TEM as shown in Figure 4. The nanoparticles of BiVO₄ and CdS presenting agglomerates were observed in Figure 4a and 4c, respectively. The high-magnification of the TEM images of the localized regions in Figure 4a and 4c are shown in Figure 4b and 4d, respectively. The clear lattice fringes could be observed, and the lattice distance was measured to be in good agreement with the (010) plane of monoclinic phase BiVO₄ and the (100) plane of hexagonal phase CdS.

**Figure 4.** TEM patterns of sample: (a, b) BiVO₄; (c, d) CdS.
3.3 Photoluminescence spectra

The photoluminescence (PL) was applied to characterize the recombination probability of photo-generated carriers in the photocatalyst. The PL peaks of BiVO₄, CdS and CV-x (x=1~4) were observed in Figure 5. The as-prepared BiVO₄ and CdS exhibited sharp emission peaks at 469 nm and 494 nm, respectively. Meanwhile, no new emission peaks were observed in CV-x compared to pristine CdS and BiVO₄. The PL intensity of BiVO₄ and CdS is significantly higher than those of CV-x, which indicates that the photo-generated carriers recombine more rapidly in single phase.

Figure 5. The photoluminescence spectra analysis of BiVO₄, CdS and CV-x (x=1~4).

3.4 Electrochemical performances

As described in Figure 6a, electrochemical impedance spectroscopy (EIS) was employed to investigate the kinetics of interfacial charge immigration of the pristine BiVO₄, CV-x (x=1~4) and pristine CdS [42]. The Nyquist curves were measured through a three-electrode system. Generally, the smaller the arc radius, the smaller the interfacial resistance as photo-generated carriers are transferred [40,43]. As the proportion of BiVO₄ ascends, the newly formed Z-scheme heterostructures caused the increase of the space separation efficiency of photo-generated carriers and significant diminution of electrochemical resistance in light of the decreasing of the radius of curvature of CV-x (x=1~4). Nevertheless, when the optimistic ratio was exceeded, the lack of effective interface electric field will lead to the slow transfer of photo-generated carriers on the basis of the increasing the radius of curvature. Consequently, when the ratio is 1:0.75 (CV-3), it is more inclined to accomplish transfer and spatial separation of photo-generated carriers towards the surface reaction sites of the photocatalyst.

Figure 6. (a) The EIS spectra of samples. (b) The M-S spectra of samples.
Figure 6b displayed the Mott-Schottky spectra of the obtained BiVO₄, Cds and CV-x (x=1–4), the measured frequency was 100 Hz. The flat band potential was determined by the tangent of the curve and the intercept of the horizontal axis voltage. Owing to the flat band potential is estimated by Ag/AgCl as reference electrode, which is equal to a normal hydrogen electrode (NHE) to be more positive 0.2V. Consequently, the flat band potential of BiVO₄, Cds and CV-x is estimated to be -0.03, 0.11, 0.08, -0.43, 0.22 and -0.51 V (vs NHE), respectively [18]. It was considered that the flat band potential is about 0.1 V more positive than the conduction band position for most n-type semiconductors, thus the conduction band position can be estimated from the flat band potential. The change in flat band potential is attributed to electron migration caused by alignment of the conduction band and Fermi level as the Z-scheme heterostructure forms. Meanwhile, the flat band potential of CV-x firstly showed a negative shifting and then displayed a positive shifting with the variation of BiVO₄ component. Generally, the negative shift could inhibit the recombination of charge carriers by enhancing the band bending at the interface [44]. Therefore, when the composite ratio is 1:0.75 (CV-3), the separation of space charge can be better promoted. In addition, the carrier concentration of the semiconductor photocatalyst can be estimated by the slope of the curve. The carrier concentration can be determined by the formula:

$$N_d = \frac{(2/e\varepsilon_0\varepsilon)(d(1/C^2)/dV)}{1}$$

Among them, $N_d$ and C are the carrier density and interface capacitance, $\varepsilon_0$ is the amount of charge carried by an electron, $\varepsilon$ is the dielectric constant, $\varepsilon_0$ is vacuum permittivity and, $V$ is the applied voltage [45]. According to calculations, the carrier densities of BiVO₄, Cds and CV-x (x=1–4) were 2.92×10²³, 7.08×10²³, 9.64×10²³, 1.55×10²⁵ and 9.46×10²³ and 6.04×10²⁴ cm⁻³, respectively. The results indicate that the formation of the Z-scheme heterostructure can effectively increase the carrier density.

3.5 Photocatalytic performance

As shown in Figure 7a, the photocatalytic properties of the obtained Cds, BiVO₄ and CV-x (x=1–4) were monitored by photodegradation of MO at 65 °C under visible light irradiation. The darkness status was maintained for 30 min to eliminate the disturbing of physical adsorption, and then the photodegradation experiment was carried out after the balance of adsorption and desorption was reached. After visible light irradiation for 150 min, the photocatalytic degradation efficiency of BiVO₄, Cds and CV-x (x=1–4) were 67.9 %, 55.8 %, 71.4 %, 72.2 %, 90.6 % and 78.6 %, respectively. Compared to BiVO₄ and Cds, the photocatalytic degradation efficiency of CV-x was significantly improved and the degradation efficiency of CV-3 reached 90.6 %. According to the Langmuir-Hinshelwood (L-H) kinetic model: $ln(C_0/C_t) = kt$, where $C_0$ and $C_t$ are MO concentration (mg L⁻¹) before and after irradiation, $t$ is time (min), $k$ is apparent reaction rate constant (min⁻¹). Photocatalytic kinetics can be represented by a pseudo-first-order kinetic model to eliminate the effect of adsorption on MO decolorization. The fitting results are shown in Figure 7b. It shows that the $k$ value of CV-3 ($k = 9.78 \times 10^{-3}$ min⁻¹) is 1.82 and 1.39 times than those of individual BiVO₄ ($k = 5.36 \times 10^{-3}$ min⁻¹) and Cds ($k = 7.00 \times 10^{-3}$ min⁻¹) under the same condition, respectively.

The photocatalytic performances of the prepared Cds, BiVO₄ and CV-x (x=1–4) were also evaluated by photodegradation of RhB at 65 °C under visible light irradiation as shown in Figure 7c. After visible light irradiation for 75 min, the degradation rates of BiVO₄, Cds and CV-x to RhB were 44.7 %, 34.2 %, 89.1 %, 95.9 %, 97.9 % and 80.1 % respectively and the degradation rate of CV-3 was still highest among all samples. According to the pseudo-first-order kinetic mode (Figure 7d), it can be seen that the reaction rate constant of CV-3 ($k = 4.39 \times 10^{-2}$ min⁻¹) is 6.2 and 9.4 times than those of BiVO₄ ($k = 7.09 \times 10^{-3}$ min⁻¹) and Cds ($k = 4.68 \times 10^{-3}$ min⁻¹), respectively. Because CV-x (x=1–4) formed direct Z-scheme heterostructure inhibiting the recombination of photo-generated carriers and providing more reaction sites, the photocatalytic activities were effectively improved. Among them, CV-3 exhibited the most superior photocatalytic activity. However, when the BiVO₄ content was further increased, the photocatalytic activity decreased. However, the photocatalytic activity decreases when the
BiVO$_4$ content is further increased, which may be caused by the insufficient composition of BiVO$_4$ and CdS and the lower conduction band of BiVO$_4$ [40]. These cycling experiments of RhB degradation were applied to examine their interaction force and possible the photo-corrosion phenomenon of sulfide and in the CV-3 as shown in Figure 7e. After three cycles of experiments, the photocatalytic degradation rate of CV-3 slightly reduced from 90.6 % to 81.1 % [46]. Therefore, the strong electrostatic attraction at the interface prevents the separation and shedding of CdS and BiVO$_4$, at the same time the Z-scheme heterostructure increase the stability of sulfide [47].

Figure 7. (a) Photocatalytic degradation of MO with the prepared samples under visible light irradiation. (b) Photocatalytic kinetic rates of MO with the prepared samples. (c) Photocatalytic degradation of RhB with the prepared samples. (d) Photocatalytic kinetic rates of RhB with the prepared samples. (e) Cycling experiments of CV-3 composite for the degradation of MO under visible light irradiation. (f-h) Photocatalytic experiment of CdS, BiVO$_4$ and CV-3 degradation of MO at different temperatures. (i) Kinetics of degradation rate of CdS, BiVO$_4$ and CV-3 with temperature. RhB and MO dye concentration: 10 mg L$^{-1}$, pH = 7.

Figures 7 (f-h) show the photocatalytic degradation of MO at 20 °C, 35 °C, 50 °C, and 65 °C of CdS, BiVO$_4$, and CV-3 under visible light irradiation. After 30 min of dark treatment, there was no particular difference in the adsorption effect of the same sample at different temperatures. After starting the irradiation, the degradation rate enhanced significantly with increasing temperature. At 65 °C, the degradation efficiency of pure BiVO$_4$ and CdS is only 67.9 % and 55.8 %, respectively, while the degradation efficiency of CV-3 has reached about 90.8 %. The degradation efficiency of CV-3 remained superior to those of BiVO$_4$ and CdS in the remaining three temperatures, except at 65 °C. It can be inferred that the rise in temperature provides sufficient activation energy to the reaction
system and increases the content of activating molecules, which is conducive to enhancing the photocatalytic degradation efficiency. Figure 7i displays the relationship between the degradation rate kinetics of CdS, BiVO₄, CV-3 and temperature. It can be clearly seen that the degradation rate kinetics is inversely proportional to the reciprocal of temperature. We know that, activation energy can be calculated by Arrhenius formula \(lnk = lnZ - \frac{E_a}{RT}\), where the \(k\) represents the degradation reaction rate, \(lnZ\) refers to the pre-factor or frequency factor, \(E_a\) is the activation energy of the reaction. According to the Arrhenius formula, the \(E_a\) values of CdS, BiVO₄ and CV-3 are 55.4 kJ/mol, 40.3 kJ/mol and 47.7 kJ/mol by linear fitting of lnk~1/T. Their activation energies are one order of magnitude. Table 1 shows the comparison of the degradation rates of CV-3 with previously reported CdS-based or BiVO₄-based photocatalysts. Obviously, this CV-3 exhibited superior degradation rates under weaker irradiation intensities and less photocatalyst content. This enhancement may be attributed to the presence of electrostatic gravity at the heterojunction of CV-3 due to promoting the transfer and separation of photo-generated carriers.

3.6 Photocatalytic mechanism of CdS/BiVO₄

The typical crystal facet features of BiVO₄ and CdS could be obtained by TEM. And the electron-hole transfer path was probed by the calculation of the electrostatic potential. Then, the surfaces of (010) and (100) were cleaved from BiVO₄ cell and CdS cell (Figure 8 and 9). Here a vacuum distance of 15 Å in model with periodicity. The electrostatic potential is calculated by the formula, \(\Phi = E_{\text{vacuum}} - E_f\), where the \(\Phi\) is the work function, \(E_{\text{vacuum}}\) is the vacuum energy level, and \(E_f\) is the Fermi energy level. The results are as follows, \(\Phi_{\text{BiVO₄}} = 6.52\) eV and \(\Phi_{\text{CdS}} = 4.81\) eV, respectively. The difference in the electrostatic potential between BiVO₄ surface and the (100) CdS surface is \(\Delta\Phi = 1.71\) eV.

**Figure 8.** Electrostatic potential of BiVO₄ slab structure (blue, red and purple atoms are V, O and Bi).
According to previous report, the difference in the electrostatic potential can be used to judge the migrating of photo-generated electrons [37]. As a result, the photo-generated electrons on the CdS can be more easily transferred to the BiVO₄ at the CV-x (x=1~4) heterojunction. Photo-generated electrons are initially migrated until the Fermi energy levels are aligned. Consequently, the upward bending of the valence band of CdS and the downward bending of the conduction band of BiVO₄ are caused by the transfer of photo-generated electrons. As mentioned above, the conduction band positions of CdS, BiVO₄ and CV-3 can be estimated to be -0.61 eV, -0.13 eV and -0.53 eV, respectively. Simultaneously, through the previously reported works by our group and other group, it can be determined that the band gaps of BiVO₄ and CdS are 2.43 and 2.40 eV, respectively [40,52]. Meanwhile, the valence band position can be calculated to be 2.30 eV and 1.79 eV respectively by \( E_{VB} = E_{CB} + E_{g} \). We can reasonably infer that the VB of CdS and the CB of BiVO₄ lead to the recombination of photo-generated carriers through the path of the Z-scheme heterojunction [46,53,54]. Thus, a direct Z-scheme heterostructure was constructed by electrostatic attraction at the interface (Figure 10).

**Figure 9.** Electrostatic potential of CdS slab structure (green and yellow atoms are Cd and S).

**Figure 10.** Schematic diagram of Z-scheme heterojunction formation mechanism of CV-3.
Under the irradiation of incident light, the photo-generated electrons in CB of BiVO$_4$ and holes in VB of CdS would migrate and recombine in the interface between BiVO$_4$ and CdS under the action of the built-in electric field, resulting in continuous accumulation of electrons and holes in CB of CdS and VB of BiVO$_4$, thus achieving the enhanced photocatalytic activity [19,40]. Meanwhile, the continuous depletion of holes in VB of CdS retards the oxidation of S$^2-$, which could restrain the photo-corrosion of the CdS component. Eventually, the photo-generated electrons in CB of CdS will generate O$_2$ with adsorbed O$_2$ at the surface, and photo-generated holes in VB of BiVO$_4$ will react with water to form OH. In the photocatalytic process, these active groups could promote the whole photodegradation process.

4. Conclusion

In summary, our study showed that this convenient and effective approach of electrophoretic deposition can form a direct Z-scheme heterostructure between CdS and BiVO$_4$, which exhibited excellent photocatalytic activities under visible light irradiation. The results of EIS and PL revealed that the CV-x system could enhance the separation and transfer of the photo-generated carriers. In the photocatalytic experiments with controlled temperature, the activation energy of CV-3 showed slight difference compared with CdS and BiVO$_4$. It demonstrates that the superior photocatalytic activities of CV-3 originate from well separation and transfer of photo-generated carriers. Besides, the cycling experiments demonstrate that the stability of CV-x can be well maintained by electrostatic attraction at the interface between BiVO$_4$ and CdS.
