We present single crystal inelastic neutron scattering measurements of the S = 1 dimerized quasi-two-dimensional antiferromagnet Ba₃Mn₂O₈. The singlet-triplet dispersion reveals nearest-neighbor and next-nearest-neighbor ferromagnetic interactions between adjacent bilayers that compete against each other. Although the inter-bilayer exchange is comparable to the intra-bilayer exchange, this additional frustration reduces the effective coupling along the c-axis and leads to a quasi-two dimensional behavior. In addition, the obtained exchange values are able to reproduce the four critical fields in the phase diagram.

PACS numbers: 75.10.Jm, 75.40.Gb, 75.30.Et

The presence of exotic ground states [1], excitations [2] and quantum phase transitions [3] in a growing number of available materials is making low-dimensional gapped frustrated quantum magnets especially topical. In some cases, the ability to tune the system Hamiltonian via external fields allows access to additional phases. For instance, the singlet-triplet gap in the spectrum can be closed via application of external magnetic fields [4, 5]. The resulting quantum critical point (QCP) separates a Bose-Einstein condensation of magnons [6, 7].

The hexagonal antiferromagnetic bilayer Ba₃Mn₂O₈ is established as a quasi two dimensional (2D) frustrated antiferromagnet with a quantum critical phase diagram [8, 9]. Rather than a single Bose-Einstein condensate phase as in S = 1/2 singlet-triplet antiferromagnets, Ba₃Mn₂O₈ has two sequential magnetically ordered phases, i.e. four zero-temperature QCPs, as a function of applied magnetic field: \( \mu_0 H_{c1} \approx 9 \text{T} \), \( \mu_0 H_{c2} \approx 26 \text{T} \), \( \mu_0 H_{c3} \approx 32.3 \text{T} \) and \( \mu_0 H_{c4} \approx 48 \text{T} \) [10, 11, 12, 13, 14]. The first (second) ordered phase for \( H_{c1} < H < H_{c2} \) (\( H_{c3} < H < H_{c4} \)) can be approximately described as singlet-triplet (triplet-quintet) condensation. The nature of these high field ordered phases fundamentally depends upon the zero field exchange paths and constants.

Powder INS measurements of Ba₃Mn₂O₈ yielded three independent exchange constants through comparison to a spherically averaged scattering intensity [10]. The dimer exchange \( J_0 \) and interdimer exchanges are illustrated in Fig. 1(b). Examining these excitations using single crystal INS, we find next nearest neighbor (NNN) interactions \( J_3 \) play a significant and heretofore unexplored role in the propagation of triplet excitations in Ba₃Mn₂O₈. Since the dispersion bandwidth only depends on the difference \( J_2 - J_3 \), we use \( \mu_0 H_{c3} \) [10, 11, 12, 13, 14] to determine the \( J_3 \) exchange. We find that both inter-bilayer exchange constants, \( J_1 \) and \( J_4 \), are important in determining the critical fields. In addition, we show that although ferromagnetic, \( J_1 \) and \( J_4 \) are competing interactions due to the geometric frustration of the triangular bilayers and the inter-bilayer exchange paths. This explains why Ba₃Mn₂O₈ is a quasi-2D magnet in spite of the fact that...
the dominant inter-bilayer coupling, $J_1$, is larger than $|J_2|$. Single crystals of Ba$_3$Mn$_2$O$_8$ were grown from a flux melt as described in Ref. 8. Five crystals with a net mass 0.372 g were coaligned using the HB1A triple-axis spectrometer (TAS) at the High Flux Isotope Reactor with a resulting mosaic of $\approx 42'$. INS measurements were performed on the SPINS cold neutron TAS at the NIST Center for Neutron Research. The instrument was configured with 80’ collimation before the sample followed by a cooled Be filter and an 80’ radial collimator. Measurements were performed with fixed final energy $E_f = 5$ meV selected by a 10.5 cm wide horizontally focusing analyzer. This configuration results in a measured elastic full width at half maximum (FWHM) energy resolution at the (0.3 0.3 3) wave vector of $\delta h\omega = 0.294(7)$ meV. The majority of our data presented here consists of constant wave vector $Q$ scans performed at $T = 1.7$ K in the (hh$l$) scattering plane.

Representative constant $Q$ scans are shown in Fig. 1(a). The data show a single resolution limited mode propagating along the $(hh4)$ direction between energy transfers $h\omega$ of 1 and 3 meV. The bandwidth and gap of the spectrum is in good agreement with values determined from powder INS measurements [10]. Measurements at several high-symmetry locations in the (hh0) scattering plane were also performed. These were made in the identical instrumental configuration with the focusing analyzer broadened to $\approx 23.1$ cm to integrate over additional scattering intensity. The broadened lineshape for $(200)$ in Fig. 1(a) reflects the broadened $Q$ resolution of the wider analyzer. As shown in Fig. 1(a), the measured scattering intensity in the (hh0) plane is very weak compared to the (hh$l$) plane.

To illustrate the dispersion and wave vector dependent scattering intensity, we combine a series of constant $Q$ scans in the image shown in Fig. 2(a)-(d). Figure 2(i) shows the path through wave vector space for these data. Figure 2(l) indicates a single dispersive mode in both the $(hh\zeta)$ and $(\zeta\zeta l)$ directions. The dispersion along the $(hh\zeta)$ wave vectors has a distinct W shape with clear minima in the vicinity of $h = 1$ and $h \approx \frac{2}{3}$ and a local maximum at the $h = \frac{1}{2}$. The dispersion along the $l$ wave vector has a periodicity of three reciprocal lattice units (rln).

126 individual constant $Q$ scans were separately fit to a single inelastic Gaussian peak. The peak positions along several high-symmetry directions are plotted in Fig. 2(a)-(d) and along several $(\zeta\zeta l)$ wave vectors in Fig. 3(a). The singlet-triplet excitation is fairly dispersive along the (00$l$) direction as shown in Fig. 2(d) and also along the $l$ direction near the zone boundary as shown in Fig. 3(a) for (0.15 0.15 $l$). However, there is almost no dispersion along $l$ for 0.3 $\leq h \leq$ 0.7. In fact for the $(\zeta\zeta l)$ scans shown in Fig. 3(a), the dispersion flattens and continuously changes phase as one moves from $\zeta = 0$ to $\zeta = \frac{1}{2}$.

The three original exchange constants determined from analysis of powder INS data do not account for the lack of dispersion along the $l$ direction near the zone center. Rather we must include the NNN inter-dimer interaction in the Heisenberg Hamiltonian $J_4$. As in the powder analysis, we use a dispersion based upon weakly coupled $S = 1$ dimers:

$$h\omega'(Q) = \sqrt{\Delta_0^2 + \frac{8}{3} \Delta_\nu J(Q) R(T)}$$

(1)

where $\nu = \{1, 0, -1\}$ denotes the spin projection $S^z$ of the triplet excitation, $J(Q)$ is the Fourier sum of interactions beyond dimer exchange, $\Delta_0 = J_0 + 2D/3$, $\Delta_{\pm 1} = J_0 - D/3$ and $R(T)$ is the thermal population difference between ground and excited states. For $S = 1$ antiferromagnetic dimers,

$$R(T) = \frac{1 - \exp(-J_0/3)}{1 + 3\exp(-J_0/3) + 5\exp(-3J_0/3)}.$$  

(2)

where $\beta = \frac{1}{kBT}$. Including the $J_4$ interaction, the Fourier sum becomes

$$\omega_1 = \cos(2\pi/3[-h + k + l]) + \cos(2\pi/3[-h - 2k + l]) + \cos(2\pi/3[2h + k + l])$$

$$\omega_2 = \cos(2\pi k) + \cos(2\pi[h + k]) + \cos(2\pi h)$$

$$\omega_4 = \cos(2\pi/3[2h - 2k + l]) + \cos(2\pi/3[2h + 4k + l])$$

$$\mathcal{J}(Q) = J_1\omega_1 + 2(J_2 - J_3)\omega_2 + J_4\omega_4.$$  

(3)

The small anisotropy $D = -0.032$ meV [9, 10] has been determined from zero-field ESR experiments [13]. For Ba$_3$Mn$_2$O$_8$ in zero magnetic field, $D$ will not change the dispersion and will only broaden the constant $Q$ scans. As shown in Fig. 1(a), $J_4$ corresponds to NNN interdimer interactions along the $c$-axis between bilayers. This exchange path is through the 12-fold coordinated Ba sites which are co-planar with the O sites associated with the Mn tetrahedra. Each of the 12-fold coordinated Ba sites participates in three such $J_4$ exchange paths. A simultaneous fit of the peak positions of the constant $Q$ scans in the (hh$l$) scattering plane yields $J_0 = 1.642(3)$, $J_1 = -0.118(2)$, $(J_2 - J_3) = 0.1136(7)$ and $J_4 = -0.037(2)$ meV. $J_2$ and $J_3$ represent interdimer exchange between the same spin dimers. They cannot be independently determined from the zero-field dispersion because $\mathcal{J}(Q)$ depends on their difference. The phase shift for triplets propagating between dimers via $J_2$ or $J_3$ (see Fig. 1(b)) is due to the opposite symmetries of the singlet (symmetric) and the triplet (antisymmetric) states under a permutation of the two sites that form the dimer. The corresponding dispersion curves shown in
Figs. 2(a)-(d) and 3(a) agree very well with the measurement. We also plot the fitted dispersion along \((\frac{1}{2}, \frac{1}{2})\) for \(J_4 = 0\) (dashed line in Fig. 3a). It is clear that the NNN exchange is needed to describe the measured dispersion. 

The dispersion minimum \(\bar{h}\omega = 1.081\) meV occurs at wave vectors \((\frac{1}{2} - \delta, \frac{1}{2} - \delta, l)\) and \((\frac{1}{2} + \delta, \frac{1}{2} + \delta, l)\) with \(\delta \approx 0.0259\). This value is similar to that determined from our powder measurements, and recent mean-field calculations.[14]

Figures 2(e)-(h) and 3(b) show the \(Q\) dependent integrated scattering intensity. Based upon the established SMA dimer model,[11] the magnetic scattering intensity for \(k_B T \ll J_0\) is

\[ I_m(Q, \omega) \propto |F(Q)|^2 \frac{1 - \cos(Q \cdot d)}{\hbar \omega(Q)} \delta(\hbar \omega - \hbar \omega(Q)), \]

where \(|F(Q)|\) is the magnetic form factor[16][17] and \(d\) is the intradimer vector: \(d = 0.1855c\). The dimer structure factor explains the lack of intensity found in the \((hk0)\) plane, i.e. \(Q_{(hk0)} \perp d\). We fit the integrated intensity to the SMA model in Eq. (4) using the dispersion found earlier and only a single multiplicative fitting parameter. The fit agrees quite well with the measured results. The dimer structure factor accounts for almost all of the scattering intensity.

The interdimer exchange corresponding to triplet propagation out of the hexagonal \(ab\)-plane is ferromagnetic for both \(J_1\) and \(J_4\), whereas interdimer coupling in the hexagonal \(ab\)-plane is entirely antiferromagnetic and consequently geometrically frustrated. We can gain insight into the consequences of the two interlayer couplings by considering the magnetic structure for \(H_{z1} < H < H_{z2}\). The in-plane geometric frustration alone leads to a \(120^\circ\) magnetic structure for a single isolated bilayer. Such a structure blocks the inter-layer couplings \(J_1\) and \(J_4\) because a spin \(S_i\) on a given bilayer interacts with the sum of three spins that are on the three different sublattices (A, B and C) of the adjacent bilayer (this sum is zero for a \(120^\circ\) structure). Consequently, the ferromagnetic interaction \(J_1\) induces a spiral phase (\(\alpha \neq 120^\circ\))[9][12] to have a net moment on each triangle. This moment is ferromagnetically coupled to the spin \(S_i\) that is at the center of the corresponding triangle (and in the next bilayer). However, such spiral distortion is not favorable for the ferromagnetic \(J_4\) term: the three spins that are nearest-neighbors of \(S_i\) in the next bilayer form a bigger triangle and the net moment of this triangle is antiferromagnetically aligned with \(S_i\). Therefore, the \(J_1\)
NNN inter-bilayer couplings are both ferromagnetic. It is clear that the antiferromagnetic interactions within the bilayer lead to a geometrically frustrated system. However for Ba$_3$Mn$_2$O$_8$ we find a novel case where ferromagnetic inter-bilayer exchange actually serves to enhance the quasi-2D behavior of the bilayer. The refined exchange constants also provide a zero-field confirmation of the high magnetic field QCPs. In addition to marked progress in understanding the quantum critical phase diagram of Ba$_3$Mn$_2$O$_8$ and its excitations and ordered states, the determined dispersion should also be applicable to other isostructural gapped magnetic compounds in the $A_3Cr_2O_8$ series where $A=$Ca$^{2+}$, Sr$^{2+}$ or Ba$^{2+}$ such as Ba$_3$Cr$_2O$_8 and Sr$_3$Cr$_2O_8.

FIG. 3: (a) Dispersion and (b) integrated scattering intensity of Ba$_3$Mn$_2$O$_8$ determined from Gaussian fits to constant Q scans. Solid lines in (a) are fits to the dispersion as discussed in the text. Dashed line in (a) is the fitted dispersion for $J_1 = 0$ resulting in exchange constants $J_0 = 1.640(8)$, $J_1 = 0.117(5)$ and $J_2 - J_3 = 0.109(2)$. Solid lines in (b) are fits to the scattering intensity as described in the text.

Exchange interaction competes against $J_4$ producing a flatter singlet-triplet dispersion along the c-axis, i.e., an effective quasi-2D like behavior. This competition also leads to smaller deviation of $\alpha$ from 120°.

Based upon the determined exchange constants and an appropriate choice of $J_3 = 0.167$ meV such that $H_{c1}$ agrees with its well determined experimental value, we are able to determine the remaining critical fields. Using a two-level approach keeping only the singlet ($S^z = 2$ quintet) and the $S^z = 1$ triplet dimer states for $H_{c1} < H < H_{c2}$ ($H_{c3} < H < H_{c4}$), we obtain values for the four critical fields: $H_{c1} = 10$ T, $H_{c2} = 27$ T; $H_{c3} = 32.75$ T; $H_{c4} = 47.75$ T. The agreement with the experimental values is quite good considering that neglecting the excited triplet $S^z = 0$, $-1$ states introduces errors of the order of 1 T. For instance, if we include the effect of quadratic fluctuations to the $S^z = 0$, $-1$ triplet states, the lowest critical field becomes $H_{c1} = \omega^2(Q_{\text{min}})/\mu_B = 9$ T in excellent agreement with the experimental value $Q_{\text{min}}$ is the wave-vector that minimizes $\omega^2(Q)$.

Through single crystal INS measurements of Ba$_3$Mn$_2$O$_8$ we find that NNN exchange interactions are significant in describing the system. The nearest and NNN inter-bilayer couplings are both ferromagnetic. It is clear that the antiferromagnetic interactions within the bilayer lead to a geometrically frustrated system. However for Ba$_3$Mn$_2$O$_8$ we find a novel case where ferromagnetic inter-bilayer exchange actually serves to enhance the quasi-2D behavior of the bilayer. The refined exchange constants also provide a zero-field confirmation of the high magnetic field QCPs. In addition to marked progress in understanding the quantum critical phase diagram of Ba$_3$Mn$_2$O$_8$ and its excitations and ordered states, the determined dispersion should also be applicable to other isostructural gapped magnetic compounds in the $A_3Cr_2O_8$ series where $A=$Ca$^{2+}$, Sr$^{2+}$ or Ba$^{2+}$ such as Ba$_3$Cr$_2O$_8 and Sr$_3$Cr$_2O_8.
