Lead-halide perovskite (LHP) semiconductors are emergent optoelectronic materials with outstanding transport properties which are not yet fully understood. We find signatures of large polaron formation in the electronic structure of the inorganic LHP CsPbBr$_3$ by means of angle-resolved photoelectron spectroscopy. The experimental valence band dispersion shows a hole effective mass of $m^* = 0.26C_6^0.02$, 50% heavier than the bare mass $m_0 = 0.17C_6$, predicted by density functional theory. Calculations of the electron-phonon coupling indicate that phonon dressing of the carriers mainly occurs via distortions of the Pb-Br bond with a Fröhlich coupling parameter $\alpha = 1.81$. A good agreement with our experimental data is obtained within the Feynman polaron model, validating a viable theoretical method to predict the carrier effective mass of LHPs ab initio.

Hybrid organic-inorganic and inorganic lead-halide perovskites (LHPs) rival conventional semiconductors in multiple optoelectronic applications. LHP-based solar cells have established energy conversion efficiencies approaching 25% [1]; light-emitting devices [2] and lasers [3] are gaining considerable interest thanks to high luminescence quantum efficiency [4]. The carrier diffusion length is exceptionally long in LHPs, reaching up to several micrometers [5,6]. This property results from the long carrier lifetimes, rather than from the carrier mobility [7]. While theory predicts small effective masses [8–13] ($\approx 0.1–0.3C_6$, where $m_e$ is the free electron mass), the reported mobilities are orders of magnitude lower than in conventional inorganic semiconductors [7,14]. The microscopic mechanism underlying this unusual combination of transport properties is possibly the interplay between carriers and the ionic perovskite lattice [7,15]. In a polar crystal, longitudinal-optical (LO) phonon modes have a sizable long-range interaction with charge carriers, resulting in the formation of so-called Fröhlich polarons [16]. The polaron, heavier than a bare carrier, has a reduced mobility, compatible with the observed transport properties [15,17]. In particular, the screening of the Coulomb potential is modified in the case of polarons, purportedly explaining the observed carrier lifetimes [17,18].

The optical properties of different LHPs are known to critically depend on the details of the lead-halide bond angles [19], highlighting the importance of carrier-lattice coupling in the photophysics of LHPs. The presence of polaron quasiparticles was indeed already proposed to model the results of several optical studies [17,18,20].

In this Letter we report on experimental evidence of polaron formation by measuring its fingerprint in the electronic structure. We concentrate on the prototypical
inorganic LHP CsPbBr$_3$, which has lately attracted interest for applications, due to better thermal and radiation stability compared to hybrid organic-inorganic LHPs [21–25]. The momentum-resolved electronic structure of CsPbBr$_3$ is determined by angle-resolved photoelectron spectroscopy (ARPES) and compared with \textit{ab initio} density functional theory (DFT). Our ARPES data provide a direct measurement of the hole effective mass ($m_{\text{exp}}$) in CsPbBr$_3$. The experiment reveals a mass enhancement of 50% compared to theory, which we attribute to electron-phonon coupling. \textit{Ab initio} simulations of electron-phonon interaction show that Pb-Br stretching modes dominate the interaction. Furthermore, our calculations provide a Fröhlich coupling parameter $\alpha = 1.81$, indicating that carriers form large polarons, and predict a mass renormalization in good agreement with experimental data.

At room temperature CsPbBr$_3$ assumes an orthorhombic lattice structure, which departs from the ideal cubic perovskite structure. The transition to the orthorhombic phase occurs below 360 K by rotation of the [PbBr$_6$]$^{4-}$ octahedra surrounding the Cs$^+$ cation [26]. The orthorhombic structure is compared to an undistorted cubic one in Fig. 1(b), showing its larger real-space primitive cell and the octahedra’s canting angle of approximately 10° [14]. High-quality single crystals of CsPbBr$_3$ were grown from liquid solution using an inverse temperature crystallization method [27]. The CsPbBr$_3$ crystals were cleaved \textit{in situ} under ultrahigh vacuum conditions. ARPES experiments were performed using extreme ultraviolet radiation from a high-harmonic laser source with a tunable photon energy between 20 and 40 eV [28,29]. All data were collected at room temperature, in the orthorhombic phase of CsPbBr$_3$, as confirmed by x-ray diffraction [30–52]. To rationalize the experimental results, we perform \textit{ab initio} calculations using the \textit{ab initio} Quantum ESPRESSO distribution [53,54]. The electronic structure was obtained at the generalized Kohn-Sham level using the hybrid functional scheme proposed by Heyd, Scuseria, and Ernzerhof [55,56] (HSE) for the exchange and correlation energy functional. The electron-phonon interaction was accounted for within the Fröhlich model [57] with parameters obtained averaging the \textit{ab initio} Fröhlich vertex [58,59]. Further details concerning the experimental methods and the DFT calculations are given in the Supplemental Material [30].

The valence band (VB) photoemission intensity distribution is plotted as a function of energy and in-plane momentum wave vectors in Fig. 1(d), for a photon energy of 37 eV. The left half of Figs. 1(e) and 1(f) shows two cuts at constant energy of the three-dimensional ARPES intensity distribution, at the valence band maximum (VBM) and 1.1 eV below the VBM. The energy zero was set at the VBM, determined from the energy of the peak maximum. Four valence band maxima are clearly resolved at the four corners ($\bar{M}$) of the surface-projected Brillouin zone (SBZ), following the periodicity expected for the cubic phase of the system, despite the structural phase transition...
to orthorhombic. This is illustrated in the right half of Figs. 1(e) and 1(f), where the data is compared to DFT calculations for the cubic phase of CsPbBr$_3$.

This is at odds with DFT calculations for the orthorhombic phase, which predicts the VBM at the $\bar{\Gamma}$ point [30,60]. To exclude matrix element effects and dispersion in the direction orthogonal to the sample surface ($k_\perp$), we performed energy- and polarization-dependent ARPES measurements [30], which reveal no signature of an additional VBM at the $\bar{\Gamma}$ point. The observation of a larger $k$-space periodicity is not compatible with the scenario of a surface reconstruction. The additional potential associated with a periodic lattice distortion generally manifests itself with the appearance of backfolded bands and gaps opening at the novel Bragg planes. However, the spectral weight transfer to the novel bands is proportional to the strength of the perturbing potential and often hardly observable [61], e.g., for the methylammonium lead triiodide perovskite (MAPbI$_3$) [62,63], where no signatures of backfolded orthorhombic bands were observed by ARPES, despite a clear orthorhombic diffraction pattern. To calculate explicitly the spectral weight transfer upon the structural distortions, we follow a band unfolding procedure proposed by Ku et al. [64] and implemented in the Quantum ESPRESSO package [65]. The calculations confirm the absence of significant spectral weight transfer to the backfolded upper valence band in the orthorhombic phase [30]. For this reason we maintain the cubic phase notation for high-symmetry points throughout the text.

The material’s band structure has been investigated as a function of the photon energy, and Fig. 2 shows the measured valence band at 33.5 eV, the VBM is found to correspond to $k_\perp \approx 0.5$ Å$^{-1}$, close to the cubic bulk $R$ point [30]. The data correspond to the band dispersion along the $\bar{\Gamma} - \bar{M} - \bar{X} - \bar{\Gamma}$ path of the surface Brillouin zone and are compared with the spectral weight of the orthorhombic bands unfolded on the cubic $X - R - M - X$ path. The upper valence band disperses for approximately 1.5 eV below the VBM, before reaching a deeper valence manifold, where bands are not individually resolved.

Although in the room-temperature orthorhombic phase the ARPES spectral weight follows qualitatively the DFT bands for the cubic phase, the band dispersion is modified by the structural distortion. In fact, the effective mass computed for the orthorhombic phase is 0.17 $m_e$, larger than the cubic phase mass of 0.12 $m_e$ [30]. To determine the experimental hole effective mass, we turn to a quantitative analysis of the upper valence band dispersion which we compare with $ab$ initio calculations for the orthorhombic structure. ARPES data along the $\bar{\Gamma} - \bar{M}$ direction are shown in Fig. 3. The VB energy distribution curves are well fitted by a Gaussian line shape whose width (which is not resolution limited) is likely determined by thermal broadening with possible contributions from disorder and orthogonal momentum dispersion. To determine $m_{\text{exp}}$, the valence band was fitted with a parabolic dispersion around the band maximum [30], the corresponding fit is shown in Fig. 3. The obtained value $m_{\text{exp}} = 0.26 \pm 0.02 m_e$ is in good agreement with optical measurements on CsPbBr$_3$ [66], where a reduced exciton mass of $m_{\text{exc}} = 0.126 m_e$ was deduced, if one assumes balanced electron and hole masses.
An important mechanism, not accounted for by the DFT calculations and relevant for polar materials, is the interaction between the photogenerated hole and longitudinal optical phonons. ARPES is sensitive to many-body interactions, encoded in the single particle spectral function \([70]\). In particular, for polaronic systems, such interactions manifest themselves as a renormalization of the bare band dispersion and with the appearance of satellite peaks in the photoemission spectrum \([71, 72]\). The satellites appear on the low-energy side of the main quasiparticle peak, at an energy separation corresponding to the relevant longitudinal optical (LO) phonon mode. In CsPbBr\(_3\) optical phonons have energies \(< 25\) meV \([73, 74]\), and replicas cannot be resolved within the experimental linewidth. In contrast, our analysis of the quasiparticle dispersion captures the effective mass renormalization, which we attribute to electron-phonon interaction.

This interpretation is supported by recent theoretical predictions for CsPbBr\(_3\) and related compounds, e.g., MAPbI\(_3\), which exhibits the same lattice structure and a similar phase diagram. Simulations of the electron-phonon interaction in MAPbI\(_3\) predict a mass enhancement of \(\approx 30\%\), where the interaction is dominated by coupling with longitudinal optical phonon modes, the most important being the Pb-I stretching and bending modes, and the librational-translational modes of the methylammonium cation \([45]\). In the fully inorganic compound, where the latter modes are absent, simulations by Miyata et al. \([15]\) show that the largest structural relaxation occurs on the Pb-Br bond distance and on the Pb-Br-Pb bond angle, resulting in a reduction of the canting angle of the PbBr\(_6\) octahedra towards the undistorted cubic lattice.

To validate this picture, we estimated the Fröhlich electron-phonon interaction, following a method recently developed for polar semiconductors \([45, 59]\). The Fröhlich vertex, which represents the matrix element for electron scattering by long-wavelength longitudinal optical phonons, can be written \([58, 59]\) as

\[
g_v(q) = -i \frac{4\pi e^2}{\Omega} \sum_k \sqrt{\frac{\hbar}{2M_k\omega_q}} \frac{\hat{q} \cdot Z_k^e \cdot e_k(q)}{\hat{\mathbf{q}} \cdot \mathbf{q}^{\infty} \cdot \hat{\mathbf{q}}} 
\]

where \(e\) is the electron charge, \(\Omega\) is the volume of the unit cell, \(M_k\) the mass of the atom \(k\), \(Z_k^e\) the Born effective charge tensor, \(\varepsilon_{\infty}\) the high-frequency dielectric tensor, and \(\omega_q\) and \(e_k(q)\) the eigenvalue and eigenvector associated with the mode \(\nu\) of momentum \(q\). We computed the material’s dielectric function, reported in Fig. 4(b), starting from \textit{ab initio} calculations of the phonon band structure of orthorhombic CsPbBr\(_3\) \([30]\). To assess the relative importance of the different phononic contributions in our calculations, the energy density of coupling \(d(g^2)/d\omega\) \([30]\) is plotted as a function of phonon energy in Fig. 4(c). The coupling is dominated by a maximum at an effective energy of \(\hbar\omega_{LO} = 18.2\) meV, in the energy region of Pb-Br...
stretches modes \([13,15]\). The effective electron-phonon coupling to such modes is obtained integrating \(d(g^2)/d\omega\) from 12 to 25 meV [see Fig. 4(b)], resulting in \(\tilde{\omega}_{\text{LO}}^2 = 3.34 \times 10^{-5} \text{ eV}^2/\text{Å}^{-2}\). Our calculation reveals that the coupling to the Pb-Br stretching modes is 2 orders of magnitude stronger compared to modes appearing in the energy range between 2 and 13 meV in Fig. 4(c), which can be associated with coupled stretching-bending modes of Pb-Br \([15]\).

Following these calculations, we proceed to estimate the mass renormalization from the Fröhlich model \([57]\), valid for a parabolic band dispersion and coupling to a single dispersionless LO phonon mode. In this limit, it can be shown that the coupling matrix elements \(g_{\nu}(\mathbf{q})\) reduce to the well-known Fröhlich coupling matrix elements \([59]\). The dimensionless Fröhlich coupling parameter, \(\alpha\), can be expressed in terms of the \textit{ab initio} approximation for the quasiparticle mass \([45,75,76]\):

\[
\frac{\tilde{\omega}_{\text{LO}}^2}{\hbar} = \frac{4\pi e^2}{\hbar n e} \left( \frac{2m_0\tilde{\omega}_{\text{LO}}^2}{\hbar} \right)^{1/2}.
\]

with \(m_0\) the bare effective mass. We obtain \(\alpha = 1.81\), which fall into the weak to intermediate coupling regime. In this regime, the Feynman polaron model provides a good approximation for the quasiparticle mass \([45,75,76]\):

\[
m_{\text{pol}} = m_0 \left( 1 + \frac{\alpha}{6} + 0.025\alpha^2 + \cdots \right).
\]

Here \(m_{\text{pol}}\) is the renormalized polaron mass, and \(m_0\) is the bare quasiparticle mass extracted from our DFT calculations. The resulting \(m_{\text{pol}} = 0.24 m_e\) is compared to the experimental result in Fig. 4. The result, in agreement with experiment within the experimental uncertainty, indicates that our model captures the main physics behind the hole quasiparticle dressing. Within the Feynman model, it is also possible to estimate the polaron binding energy and radius to be 34 meV and 58 Å, respectively. Thus, the polaron resulting from an excess hole in CsPbBr\(_3\) single crystals is large, extending over several lattice unit cells. We note that these simple estimates of polaronic radius and binding energy could be refined by a recently developed polaron model, capable of computing the polaron wave function \textit{ab initio} \([77]\). Interestingly, in the case of CsPbBr\(_3\) nanocrystals, signatures of hole self-trapping were reported \([78]\), suggesting that the electron-phonon interaction in LHPs’ nanostructures may be altered \([79,80]\). The adopted theoretical method can be readily generalized to multiple coupled LO phonon modes \([45]\), as in the case of hybrid organic-inorganic LHPs. Therefore, we expect it to be capable of predicting the carrier effective masses in the whole family of LHPs.

In conclusion, our work provides the first experimental reference for the momentum-resolved electronic structure of CsPbBr\(_3\) in the orthorhombic phase. Fits of the electronic dispersion provide an experimental value for the effective mass \(m_{\text{exp}} = 0.26 \pm 0.02 m_e\), which we found to exceed the theoretical result of \(m_0 = 0.17 m_e\). The observed mass renormalization is ascribed to electron-phonon interaction dominated by Pb-Br stretching modes, responsible for the formation of large Fröhlich polarons. \textit{Ab initio} electron-phonon coupling calculations are in quantitative agreement with the experiment, demonstrating that the employed theoretical method can correctly predict the carrier effective mass of LHPs from first principles. Our findings provide direct experimental evidence in the electronic structure that charge carriers in single-crystalline LHPs form large polarons and that the corresponding modification to the microscopic scattering rates must be taken into account to explain the exceptional transport properties of LHPs.
