ABSTRACT

We identify a spectroscopic sequence of galaxies, analogous to the Hubble sequence of morphological types, based on the Automatic Spectroscopic K-means-based (ASK) classification. Considering galaxy spectra as multidimensional vectors, the majority of the spectral classes are distributed along a well-defined curve going from the earliest to the latest types, suggesting that the optical spectra of normal galaxies can be described in terms of a single affine parameter. Optically bright active galaxies, however, appear as an independent, roughly orthogonal branch that intersects the main sequence exactly at the transition between early and late types.

Key words: methods: data analysis – methods: statistical – galaxies: fundamental parameters.

1 INTRODUCTION

It is well known that galaxies can be classified into a small number of morphological types, arranged into a well-defined sequence. The scheme proposed by Hubble (1926), still widely in use today, is based on the optical appearance of galaxy images, and it divides the galaxy population into ellipticals, lenticulars and spirals, with the irregular class encompassing all the objects that do not fit into any of the other categories. It focuses on the symmetry of the galaxy, the concentration of the light towards the centre and the presence of other features such as discs, bars and spiral arms. The Hubble sequence, also known as the Hubble tuning fork, smoothly connects the different morphological classes. Ellipticals, regular spirals and barred spirals occupy three different arms of the sequence, intersecting at the lenticular class. Irregular galaxies are more difficult to accommodate, but they are usually placed at the end of the spiral branches.

The Hubble sequence correlates with the colours of the galaxies, with ellipticals tending to be red and spirals tending to be blue (Humason 1931; Hubble 1936; Morgan & Mayall 1957). The relationship, however, presents a large scatter (Connolly et al. 1995; Sodre & Cuevas 1997; Ferrarese 2006); about half of the red galaxies are actually discs (Masters et al. 2010; Sánchez Almeida et al. 2011), and blue ellipticals are not so rare as one may naively think (e.g. Schawinski et al. 2009; Huertas-Company et al. 2010). Many works have tried to relate the spectral energy distribution (SED) of a galaxy to its position along the Hubble sequence. The results are varied, and they are probably affected by the scatter of the relationship between morphological type and spectroscopic class. Morgan & Mayall (1957) assigned the blue part of the visible spectrum to stellar classes from A to K, finding a clear relationship in the vein mentioned above. Aaronson (1978) shows how the visible and infrared colours of galaxies along the Hubble sequence can be understood as a one-parameter family, in terms of the superposition of spectra of A0V dwarf stars and M0III giants. Bershady (1995) points out that a simple model consisting of two stellar spectral types can reproduce the observed broad-band colours, but only if the spectral types are allowed to vary, which implies that the family is not one dimensional. Similar conclusions are also reached by Zaritsky, Zabludoff & Willick (1995) using stellar spectrum fitting.

One of the most popular spectral classification methods is principal component analysis (PCA). It is fast and robust, and it has a sound mathematical foundation (see e.g. Everitt 1995). For a given data set, PCA finds the smallest possible set of orthogonal eigenvectors that reproduce the data within a certain accuracy. In the case of galaxy spectra, Connolly et al. (1995) claim that the first two eigenvectors suffice to represent most galaxies, and that the resulting spectral types can be described in terms of a one-parameter family. Based on the PCA decomposition of a much larger galaxy sample, containing more than 10\(^5\) spectra, Yip et al. (2004) highlight the importance of the third eigenvector and summarize the galaxy spectra in terms of two independent angular variables. In other words, the galaxies are contained within a three-dimensional volume, given by the linear combination of the first three eigenvectors.

However, it is not obvious whether the galaxy distribution is indeed three dimensional, or it is confined to a non-linear manifold of lower dimensionality, immersed in the three-dimensional space. Here we study the multidimensional distribution of galaxy spectra and explore the possibility that different galaxy types may be arranged into a spectroscopic sequence, analogous to the morphological Hubble tuning fork. The first problem, of course, is how to detect such a sequence, if it existed, in a space with as many dimensions as data points in the spectrum. Then, if galaxies did indeed form a well-defined spectroscopic sequence, it would be extremely interesting to quantify its multidimensional structure. Would all galaxies be arranged along a single curve or along several branches or along a hyperplane (or a higher dimensionality subspace)?
In principle, the dimensionality of the sequence is related to the number of parameters that are necessary in order to fully describe a galaxy spectrum. If all their observable properties depended on only one single degree of freedom, galaxies would describe a one-dimensional curve in spectral space, no matter how complicated. For two parameters, the galaxy population would define a "fundamental hypersurface" (not necessarily a plane), and so on. It must be noted, though, that these subspaces may or may not be fully occupied. Galaxies could be arranged in several disconnected clumps, more or less randomly distributed in spectral space, or be confined to a certain region defined by some set of inequalities.

In practice, finding, let alone characterizing, a non-linear two-dimensional hypersurface is by no means a trivial task, and even more so for structures in many dimensions (see e.g. Ascasibar & Binney 2005; Ascasibar 2008, 2010; Vanderplas & Connolly 2009). However, the existence of several relations, such as the Tully & Fisher (1977) relation for spiral galaxies, or the Faber & Jackson (1976) relation and the Fundamental Plane (Djorgovski & Davis 1987) for elliptical galaxies, provides encouraging evidence that galaxies can be described in terms of very few independent parameters (Smolčić et al. 2006; Disney et al. 2008; Tollerud et al. 2011). As mentioned above, previous studies based on PCA have concluded that only the first two or three linear eigencoefficients are necessary in order to reproduce the main features of the galaxy distribution in spectral space (e.g. Connolly et al. 1995; Galaz & de Lapparent 1998; Castander et al. 2001; Yip et al. 2004; Ferreras et al. 2006).

The present work follows a different approach, based on the publicly available1 Automatic Spectroscopic K-means-based (ASK) classification of all the galaxy spectra in the seventh data release of the Sloan Digital Sky Survey (SDSS/DR7; Stoughton et al. 2002; Abazajian et al. 2009). A thorough description of this classification scheme is provided in Sánchez Almeida et al. (2010), where the reader is referred to for further details, but the main aspects are summarized in Section 2 for the sake of comprehensiveness. We investigate whether galaxies form a continuous, single-parameter sequence by studying the minimal spanning tree (MST) of the template vectors defining the ASK classes. The details of the computation of the MST are given in Section 3, and Section 4 is devoted to the identification of a possible spectroscopic sequence. A quantitative characterization and its physical interpretation are discussed in Section 5, and our main conclusions are then succinctly summarized in Section 6.

2 THE ASK CLASSIFICATION

The ASK classes are the result of classifying all the galaxies with spectra in the SDSS/DR7. Those with redshift smaller than 0.25 are transformed in a common rest-frame wavelength scale, and then renormalized to the integrated flux in the SDSS g filter. These two are the only manipulations the spectra undergo before classification. The classification is driven only by the shape of the spectra, and these two corrections remove the obvious undesired dependencies on the redshift and apparent magnitude of the galaxy. Sánchez Almeida et al. (2010) deliberately avoid correcting for other known effects requiring modelling and assumptions (e.g. dust extinction, seeing or aperture effects), in the spirit of the rules for a good classification put forward by Sandage (2005), where it is pointed out that physics must not drive a classification. Otherwise, the arguments become circular when the classification is used to infer the underlying physics.

The classification algorithm used, k-means, is a well-known, robust workhorse, commonly employed in data mining, machine learning and artificial intelligence (see e.g. Everitt 1995; Bishop 2006). Its computational efficiency was an important asset in order to carry out the simultaneous classification of the full data set (~12 GB). The algorithm works by iteratively assigning each galaxy to the nearest class in spectral space and re-evaluating the class template spectrum as the average over all the class members. In the end, 99 per cent of the galaxies can be assigned to only 17 major classes, with 11 additional minor classes describing the remaining 1 per cent. The actual number of classes has some uncertainty, although it is automatically provided by the algorithm, which always renders between 15 and 19 major classes. The template spectra vary smoothly and continuously, and they are labelled from 0 to 27 according to their (μ−g) colour, from redder to bluer. It is unclear whether the ASK classes represent genuine clusters in the 1637-dimensional classification space, or they partake a continuous distribution (see the discussion in Sánchez Almeida et al. 2010, as well as Section 5). The class templates cover all the possible spectral shapes, and we use them in our search for a sequence. Since we are not interested in the occupation distribution along such a sequence, all templates are treated equally, even though each class contains a different number of SDSS/DR7 galaxies.

3 MINIMAL SPANNING TREE

The MST of a graph (e.g. Kruskal 1956) is the set of edges that connect all the vertices in the graph at a minimum cost, defined as the sum of the individual costs of all the edges included in the tree. In our case, these individual costs are given by the differences between the template spectra, and the MST can be thought of as the shortest possible ‘road network’ connecting all spectral classes.

Although real life is a little bit more complicated (see below), one may expect that, if galaxies, and thus classes, were roughly arranged into a single curved line, the MST would be ideally suited to identify such a multidimensional sequence. For example, if A, B, C, D and E are different types of galaxy, forming the sequence A-B-C-D-E, this would be their MST, and it can be proven that any other combination of edges would result in a longer total distance. In this example, the extreme classes A and E would have just one connection, whereas the intermediate types B, C and D would have two. Moreover, the distance between the next-to-sequential classes (e.g. A and C) must be larger than both AB and BC. If A, B and C are aligned along a straight line, the equality AC = AB + BC will hold, whereas for a curved line AC < AB + BC.

If the galaxy distribution had more than one dimension, some classes would become ‘tree nodes’ featuring three or more connections. If the subspaces defined by the galaxies is fully occupied, there will be a large number of nodes, and it would be difficult to obtain much information about its structure from the MST alone. On the other hand, a small number of nodes would imply that galaxies are arranged into a few discrete ‘branches’ with different orientations.

The MST of ASK classes is shown in Fig. 1, using eight slightly different definitions of the distance in spectral space. In the top panels, we assume the Euclidean metric

\[
d^2_{\text{AB}} = \sum_{i=1}^{N_T} \left[ C_B(\lambda_i) - C_A(\lambda_i) \right]^2,
\]

1 ftp://ask-galaxy@ftp.iac.es/
MST of the ASK classes, based on the Euclidean (top) and Manhattan (bottom) distance between template spectra, considering, from left to right, the full wavelength range, only the red part ($\lambda > 6000$ Å), the blue part ($\lambda < 6000$ Å) and the same bands used to define the ASK classes. The full table is available in the electronic version (see Supporting Information).

Table 1. Template spectrum of ASK class 5 and basis vectors $\Delta_T$ and $\Delta_A$ as a function of wavelength. Last column is a binary flag indicating whether that particular wavelength is included in the bands used to define the ASK classes. The full table is available in the electronic version (see Supporting Information).

| 3807.03       | 6.310e-01 | 6.484e-03 | -2.825e-05| 0    |

whereas the Manhattan distance

$$d_{AB} = \sum_{i=1}^{N_5} | C_B(\lambda_i) - C_A(\lambda_i) |$$

(2)

has been used in the bottom panels. In both cases, $d_{AB}$ denotes the distance between classes A and B, and $C_5(\lambda)$ is the spectral template of class $X$, evaluated at a wavelength $\lambda$. We investigate different criteria to select the set of $N_5$ discrete wavelengths involved in the computation in order to test the stability of the results: the whole SED between 3800 and 9250 Å ($N_5 = 3850$), only the bluest part ($\lambda < 6000$ Å, $N_5 = 1977$), the red part ($\lambda > 6000$ Å, $N_5 = 1873$) and the same 17 bands that were used to define the ASK classification ($N_5 = 1637$, see table 1 in Sánchez Almeida et al, 2010, for the precise definition of the bandpasses). Note that, in each case, the dimensionality of the data space is given by the value of $N_5$.

The fourth option – using the spectral range used to define the ASK classification – is arguably the most natural. Using the spectral range to the red end, where the mean spectra of each class have been extrapolated, or the blue end, which is often dominated by the presence of strong emission lines, seems to be poor choices that probably introduce some noise in the resulting MST. Also, the Euclidean metric, where differences add in quadrature, seems to be more appropriate for comparing two spectra than the Manhattan distance. We simply use all these different definitions in order to test the stability of our results. Although the solution is far from being unique (the exact ordering of the classes depends on the adopted definition), the overall picture is fairly robust: according to the MST, the ASK classes representing the galaxy population in the SDSS seem to be distributed along three main spectroscopic branches, or, alternatively, along a main spectroscopic sequence with one ramification.

The longest branch, both in terms of the number of classes and the extent measured by the Euclidean distance (i.e. differences in the template spectra), is composed of ASK types 15, 17, 20, 21, 25, 27, 26, 24, 23, 22, 18 and 19. The position of these classes on the principal component plane, as well as on the colour–colour and BPT (Baldwin, Phillips & Terlevich 1981) diagrams (see Figs 7 and 8) suggests that this branch corresponds to the sequence of dwarf irregular galaxies. It merges smoothly with the location in spectral space occupied by normal spirals, represented by ASK classes 16, 14, 13, 12 and 9. Early-type galaxies (classes 0, 2, 3 and 5) are also grouped together in another branch for all measures of the distance, and the same can be said of the active galaxy types 8, 7, 6, 11 and 10. All three branches (early type, late type and active) seem to converge around classes 9, 10 or 12, depending on the definition used. Classes 1 and 4 seem to be outsiders in the main red sequence, and we are currently investigating the possibility that they are associated to heavily dust reddened spirals (Sánchez
Figure 2. Template spectra of several ASK classes representative of the early-type branch (top panel), late-type branch (middle panels) and active branch (bottom panel). $C_X$ denotes the spectral template of class X.

Almeida et al. 2011). Samples of spectra that are representative of each branch are plotted in Fig. 2.

4 A SPECTROSCOPIC SEQUENCE

We argue that the three independent branches we have identified trace an underlying spectroscopic sequence, analogous to the Hubble tuning fork of galaxy morphologies, and the subtle differences between the MST obtained for different definitions of the distance are due to the presence of random deviations of the individual galaxy spectra with respect to the average behaviour of the sequence.

In other words, our branches are not ideally thin hyperlines in the data space, but ‘hypertubes’ with a certain, variable thickness, where the contributions of intrinsic physical dispersion of the galaxy properties as well as extrinsic observational errors add in quadrature.

Figure 3. Results of the $k$-means algorithm for a random distribution of points in two dimensions (see text). Class centres are shown by the open boxes.

Given the large number of objects involved in most ASK classes, measurement errors have a negligible effect on the mean spectrum, but they make a significant contribution to the dispersion of the individual galaxies around the mean (although the error in the mean spectrum decreases as the square root of the number of observations, the actual dispersion of the distribution is independent of the number of galaxies).

Due to the finite thickness of the branches, the ASK classes derived from the $k$-means algorithm will not be aligned along the centres of these hypertubes, but they will alternate along their boundaries. This can be easily illustrated by a simple experiment, where we set up a random distribution of data points that corresponds to a hypertube in two dimensions. The first coordinate varies uniformly from 0.1 to 0.9, and the second follows a Gaussian distribution centred at 0.5 with a standard deviation of 0.1. The data points and the centres of the final classes returned by the $k$-means algorithm are plotted in Fig. 3 as dots and open boxes, respectively. This configuration, where classes (i.e. template spectra) alternate between the boundaries of the distribution rather than tracing the centre, will occur whenever the dispersion around the mean is comparable to the typical interclass distance. During the first iteration, the classes are initialized at the locations of randomly picked data points. Then, each class collects the points in its Voronoi cell, and its position is updated to the new centre of mass. The process is repeated until the classes arrange themselves into the pattern shown in Fig. 3, which roughly corresponds to the most efficient packing in two dimensions.

In the general case, the MST will be able to pinpoint a sequence with a finite thickness, but it will zigzag through the distribution rather than crossing it along a more or less straight line. More precisely, the angle between the directions of two consecutive edges (say, AB and BC) may not necessarily be small, and the distance AC may be comparable to both AB and BC. On the contrary, the segments AC, CE, EG, etc. – which do not belong to the MST – trace the boundary of the distribution and, unless there is a sharp turn, the angles between them will be typically smaller than the angles between consecutive edges in the MST.

We therefore investigated all the distances and angles between consecutive vertices in any of the four variants of the MST defined with the Euclidean metric distance shown in the previous section. A schematic representation is plotted in Fig. 4 (see also Appendix A). Being a projection of a non-linear multidimensional structure, it is necessarily not to scale, but we have tried to reproduce actual...
Do galaxies form a spectroscopic sequence?

Our main result is the identification of a spectroscopic sequence with three separate branches, which represent – at least in a qualitative sense – early-type, late-type and active galaxies. However, several questions remain open: how many parameters are necessary in order to fully specify the spectral properties of a galaxy? How could one compute their value, and what is their physical meaning? What do they tell us about galaxy formation and evolution?

Concerning the first question, the configuration of the ASK classes in spectral space suggests that the optical spectra in the SDSS/DR7 have only two degrees of freedom. An interpretation in terms of a single parameter would be that the putative one-dimensional curve in spectral space marches through the early-type galaxies, climbs up and down the active branch, and then moves on towards the late types. Alternatively, and arguably more likely, it would also be possible that there is a main sequence going from early- to late-type galaxies, but some of them (especially those in the green valley; see e.g. Salim et al. 2007) may be temporarily found in an active state that takes them out of the main sequence. In this scenario, the optical spectrum of a galaxy can be accurately described in terms of one discrete parameter (whether the galaxy belongs to the ‘normal’ or the ‘active’ branches) and one real number characterizing its position along the corresponding sequence.

This interpretation is reinforced when one tries to find a bidimensional projection that captures the main features of the spectral classification. After some experimentation, we have selected the hyperplane defined by ASK classes 0, 5 and 8, corresponding to a typical early-type galaxy, an object in the green valley and an extremely active galaxy, respectively. Looking at the distances and angles between the classes, one can easily verify that classes 5, 6, 7 and 8 are roughly aligned along a more or less straight line, at an angle of 102° (almost perpendicular) with respect to the segment connecting classes 5 and 0. We have thus selected the template of the green valley class 5 as the origin of coordinates. The axis towards class 8 provides a measure of galaxy activity, and we have set the normalization so that this class represents the unit value. For a
galaxy with SED $S(\lambda)$, the activity $A$ is defined as the scalar product

$$A = \sum_{i=1}^{N_c} [S(\lambda_i) - C_5(\lambda_i)] A_4(\lambda_i),$$  

(5)

with the vector

$$A_4(\lambda_i) = \frac{C_6(\lambda_i) - C_5(\lambda_i)}{\sum_{j=1}^{N_c} [C_6(\lambda_j) - C_5(\lambda_j)]^2}.$$  

(6)

On the other hand, the axis defined by class 0 can be used to quantify the spectral type of the galaxy in a similar way:

$$T = \sum_{i=1}^{N_c} [S(\lambda_i) - C_3(\lambda_i)] \Delta_T(\lambda_i),$$  

(7)

where

$$\Delta_T(\lambda_i) \propto [C_0(\lambda_i) - C_3(\lambda_i)]$$

$$= \sum_{j=1}^{N_c} [C_0(\lambda_j) - C_3(\lambda_j)] \Delta_A(\lambda_j) \Delta_A(\lambda_i)$$  

(8)

is orthogonal to $\Delta_A$, and it is normalized so that the type of class 0 is equal to $-1$, i.e. we choose the scaling constant in equation (8) so that

$$\sum_{i=1}^{N_c} [C_0(\lambda_i) - C_3(\lambda_i)] \Delta_T(\lambda_i) = -1.$$  

(9)

The spectral template of class 5, together with the basis vectors $\Delta_A$ and $\Delta_T$, are represented in Fig. 5, and the location of ASK classes in the galaxy type–activity plane is plotted in Fig. 6. The shape of the spectroscopic sequence is evident in this representation, which has the advantage that its two parameters are easy to evaluate for any galaxy (numeric values for $C_5$, $\Delta_A$ and $\Delta_T$ are provided in Table 1) and have a very clear physical meaning: the spectral type quantifies the evolutionary state of the galaxy, while the activity component reflects the presence of warm ionized gas. An interesting feature that was not obvious from the study of the angles between edges in the MST is that the end of the late-type branch turns into a direction that is roughly parallel (more precisely, forms an angle of 20°) in spectral space to the axis defined by the active galaxies. From Fig. 5, we immediately see that this is due to the presence of strong emission lines that make a significant contribution to the overall luminosity, but both branches can be easily identified with the well-known active galactic nucleus (AGN)/starburst dichotomy in the BPT diagram.

The projection of our spectroscopic sequence on to the BPT diagram, as well as the colour–colour plane defined by $(u - g)$ and $(g - r)$, is shown in Fig. 7. The early and late branches correspond to the red sequence and the blue cloud in the colour–colour plot, respectively, and all the active galaxies are located approximately at the same place, in the region of the green valley. On the other hand, AGN can be neatly separated from the late-type galaxy population in the BPT diagram, but in this case the early-type branch is absent because the intensity of the H$\beta$ line is too faint (in fact, it is observed in absorption for ASK classes 0, 2 and 3). The projection on to the type–activity plane has the advantage that the full structure of the sequence, with its three branches, can be represented simultaneously.

Another interesting space for projection is the volume defined by the first three eigenvectors resulting from a PCA (Yip et al. 2004). As in the case of the colour–colour and BPT diagrams, the one-dimensional nature of the galaxy distribution is also encoded in the configuration of the ASK classes within the three-dimensional volume defined by the first PCA coefficients $(a_1, a_2, a_3)$, as well as in the projections of the spectroscopic sequence on to the three orthogonal planes $(a_1, a_2)$, $(a_1, a_3)$ and $(a_2, a_3)$ shown in Fig. 8. Note that the projection of the curve in the first two eigenvalues $(a_1, a_2)$ is qualitatively similar to the location of the classes in the type–activity plane (Fig. 6). This fact connects our sequence with the finding by Connolly et al. (1995) that most galaxy spectra form a one-parameter family defined by the ratio between the first two eigenvalues. The original PCA-based sequence does not include the active branch we have identified, although it can be guessed in Fig. 4 of Yip et al. (2004).

It is convenient to emphasize that the parameters $A$ and $T$ are not meant to describe the galaxy spectra by themselves. More precisely,

$$S(\lambda_i) \neq C_5(\lambda_i) + A \Delta_A(\lambda_i) + T \Delta_T(\lambda_i),$$  

(10)

in contrast to the PCA decomposition. Their purpose is merely to provide a quantitative, continuous, linear mapping between the
Do galaxies form a spectroscopic sequence?

Figure 7. The spectroscopic sequence in the colour–colour (top panel) and BPT (bottom panel) diagrams.

SED of a given galaxy and our spectroscopic sequence. Although a detailed discussion is beyond the scope of the present work, the position of a given galaxy in the type–activity plane may be used for assigning it to the appropriate branch, as well as determining its position along the corresponding one-dimensional curve. The galaxy spectrum could then be recovered by interpolating the templates of the nearest ASK classes, but the procedure is less straightforward than PCA.

Our results are consistent with other approaches to galaxy classification, but they highlight the remarkably few degrees of freedom that are necessary in order to characterize optical spectra. Out of the several thousand dimensions of the data space, the vast majority of SDSS galaxies are confined to just two one-dimensional curves, contained in a three-dimensional Euclidean volume.

While it is well known that the structure of dark matter haloes can be described in terms of one or two free parameters (see e.g. Ascasibar & Gottl"ober 2008, and references therein), related to the statistical properties of the primordial perturbations of the density field (e.g. Ascasibar et al. 2004; Ascasibar, Hoffman & Gottl"ober 2007), it is somewhat surprising that galaxy formation, with all the complex physical processes involved, does not seem to introduce additional degrees of freedom. In our opinion, understanding why the optical SED of a galaxy contains so little information is an important piece of the puzzle of galaxy formation and evolution, and it poses a very strong constraint on the number of free parameters that are available to theoretical models.

Finally, let us note that, like the Hubble morphological sequence, the spectroscopic sequence presented here provides a snapshot of the distribution of galaxies in spectral space at the present day, but it does not imply an evolutionary track, nor does it contain any temporal information whatsoever. Galaxies of type 9 are similar to galaxies of type 10, and these, in turn, have spectra that are close to those of galaxies of type 11, but this does not mean that they turn into one another.

Nevertheless, our main sequence can be interpreted in terms of the average age of the stellar population, with younger galaxies corresponding to larger values of the spectral type. The almost perpendicular location of the active branch with respect to the main sequence suggests that optically selected AGN are associated with one particular stage of galactic evolution, in agreement with earlier results (e.g. Schawinski et al. 2007, 2010) and consistent with a scenario where quasar activity marks the termination of star formation and the transition from late to early type (see e.g. Hickox et al. 2009, and references therein). If this is true, the type–activity diagram – and the spectroscopic sequence – will probably have a similar form at high redshift, although each branch would be located in a different region of the spectral space and populated by galaxies of very different physical properties.

6 CONCLUSIONS

In this work, we have investigated the distribution of galaxies in spectral space. More precisely, we have computed the MST of the
class templates in the ASK classification of SDSS/DR7 data. By studying the distances and angles in spectral space between different galaxy types, it is found that galaxies in the local Universe are distributed along a spectroscopic sequence with three independent branches. These branches contain the spectra of early-type, late-type and active galaxies, and they intersect in the spectral region corresponding to the ‘green valley’.

This configuration contains two degrees of freedom: one discrete parameter that determines whether a galaxy belongs to the ‘normal’ (either early- or late-type) part of the sequence or to the ‘active’ branch, as well as one continuous affine parameter that describes the position of the galaxy along its one-dimensional branch. We interpret the normal branches as a main galactic sequence, described in terms of one single affine parameter indicative of the evolutionary state of the object (a combination of mean stellar age, gas abundance and chemical composition). At some point in the evolution of a galaxy, star formation stops, and the object moves from the late-type to the early-type branch. During that phase, some galaxies can also be found in the active branch. In agreement with previous work, we find that optical AGN activity is exclusively associated with that particular period.

We have verified that our results are robust with respect to different definitions of the distance between galaxy spectra. A straightforward prescription and a set of basis vectors are provided in order to quickly evaluate the spectral type and activity of a given galaxy. In the future, we would like to study the relation between spectral type and optical morphology for SDSS galaxies and to apply the same technique to a sample of objects at higher redshifts.

ACKNOWLEDGMENTS

The authors would like to thank the referee for a thorough, constructive report that led to significant improvements in the manuscript, as well as A. I. Díaz, C. Jones, W. Forman, R. Terlevich, C. Muñoz-Tuñón and M. García-Vargas for several useful comments and discussions.

This work has been funded by projects AYA 2007-67965-C03-03, AYA 2007-67965-C03-01, AYA 2007-67752-C03-01 and CSD 2006-00070 (Spanish Ministry of Science, Technology and Innovation).

APPENDIX A: DISTANCES AND ANGLES BETWEEN ASK CLASSES

Given the large amount of data plotted in Fig. 4, here we represent the early, late and active branches of our spectroscopic sequence in Figs A1, A2 and A3, respectively. For the sake of clarity, distances

![Figure A1. Distances (left) and angles (right) between the ASK classes of the early-type branch.](https://example.com/image.png)
Do galaxies form a spectroscopic sequence?

Figure A2. Distances (left) and angles (right) between the ASK classes of the late branch.

Figure A3. Distances (left) and angles (right) between the ASK classes of the active branch.

and angles between the different ASK classes are shown in separate panels.

SUPPORTING INFORMATION

Additional Supporting Information may be found in the online version of this article.

Table 1. Template spectrum of ASK class 5 and basis vectors $\Delta_T$ and $\Delta_A$ as a function of wavelength.
