Motivations.—The recent detection of B-modes in the polarization of the cosmic microwave background (CMB) by BICEP2 [1] indicates a high level of primordial tensor modes. This requires [2] a large excursion of the inflaton during inflation \( \Delta \phi \gtrsim M_{\text{pl}} \), which challenges the naive expectation that higher-dimension operators suppressed by powers of \( M_{\text{pl}} \) spoil the slow-roll conditions. While, before BICEP2, the crucial question for inflation was “large or small \( r \)?” we are now facing a new dichotomy: “\( \phi^2 \) or not \( \phi^2 \)?” The two possibilities are qualitatively different. A large field model that is not quadratic, say \( V \propto \phi^{2/3} \), suggests an interesting UV mechanism, such as monodromy inflation [3], for instance. If data will, on the other hand, favor a quadratic potential, the simplest explanation will be that inflation occurs at a generic minimum of a potential whose typical scale of variation is \( M_{\text{pl}} \) or not \( M_{\text{pl}} \)? We comment on the relevance of non-Gaussianity after BICEP2 results.

The simplest inflationary model \( V = \frac{1}{2} m^2 \phi^2 \) represents the benchmark for future constraints. For a quadratic potential, the quantity \( (n_s - 1) + r/4 + 11(n_s - 1)^2/24 \) vanishes (up to corrections which are cubic in slow roll) and can be used to parameterize small deviations from the minimal scenario. Future constraints on this quantity will be able to distinguish a quadratic potential from a pseudo-Nambu-Goldstone boson with \( f \lesssim 30 M_{\text{pl}} \) and set limits on the deviation from unity of the speed of sound \( |c_s - 1| \lesssim 3 \times 10^{-2} \) (corresponding to an energy scale \( \Lambda \gtrsim 2 \times 10^{10} \text{ GeV} \), and on the contribution of a second field to perturbations \( \lesssim 6 \times 10^{-2} \)). The limiting factor for these bounds will be the uncertainty on the spectral index. The error on the number of e-folds will be \( \Delta N \gtrsim 0.4 \), corresponding to an error on the reheating temperature \( \Delta T_{\text{rh}}/T_{\text{rh}} \approx 1.2 \). We comment on the relevance of non-Gaussianity after BICEP2 results.

...
If we take the measurement of the tilt from Planck [9] $n_s - 1 = -0.0397 \pm 0.0073$ and the recent value of $r$ measured by BICEP2 [1] $r = 0.20^{+0.07}_{-0.05}$, the lhs of Eq. (1) is equal to $0.01 \pm 0.02$ \cite{footnote4}. Optimistically we can assume we will be able to measure $r$ with a precision of 1\% \cite{footnote5}. Regarding $n_s - 1$, future experiments such as EUCLID \cite{footnote6} or PRISM \cite{footnote7} should be able to go down to a $10^{-3}$ error. Therefore, the uncertainty on the quantity above will be $\sim 10^{-3}$, dominated by the error on the spectral index. Notice that different experiments are sensitive to different scales $k$. Given that Eq. (1) is independent of $N$, it is valid on any scale provided that both $n_s$ and $r$ are evaluated at the same $k$. Therefore, it is important to keep in mind that the experimental results have to be properly combined at the same scale\cite{footnote8}.

Let us now study what these futuristic limits will imply for deviations from the simplest model of the Universe.

**Pseudo-Nambu-Goldstone boson potential.**—A PNGB has a potential of the form $V = \Lambda^4 F(\phi/f)$ \cite{footnote9}, where $\Lambda$ is the scale of breaking of the approximate shift symmetry, $F$ is a periodic function and $f$ is the decay constant. The simplest example is given by

$$V(\phi) = \Lambda^4 \left[ 1 - \cos \left( \frac{\phi}{f} \right) \right],$$

where $f$ has to be bigger than $M_{pl}$ in order for the slow-roll conditions to be satisfied and for very large $f \gg M_{pl}$ the model becomes indistinguishable from a $\phi^2$ potential. For this potential, Eq. (1) will not be exactly zero. It is easy to calculate the leading correction in slow roll and for $M_{pl}/f \ll 1$

$$n_s - 1 = -\frac{2}{N} + O \left( \frac{M_{pl}}{f} \right)^4, \quad r = \frac{8}{N} - 4 \left( \frac{M_{pl}}{f} \right)^2. \tag{3}$$

This gives a correction to Eq. (1)

$$(n_s - 1) + \frac{r}{4} + \frac{11}{24} (n_s - 1)^2 = -\left( \frac{M_{pl}}{f} \right)^2. \tag{4}$$

If the error on the lhs is of order $10^{-3}$, this translates into the limit $f \gtrsim 30 M_{pl}$. This would convincingly suggest there is a parametric separation between the two scales, which the UV theory would have to address. To illustrate this point, in Fig. 1 we present a plausible forecast for the future observations in the $(n_s, r)$ plane together with the predictions of natural inflation for different values of $f$.

---

\footnote{4} This number has to be taken with great caution because it does not include foreground subtraction in BICEP2 result. If one uses Planck data only, the lhs of Eq. (1) is compatible with zero at $\sim 2\sigma$.

\footnote{5} This is the case also for BICEP2 and Planck, but with the current errors this difference is negligible.

\footnote{6} In the extra-dimensional model of Ref. \cite{footnote10}, the explicit form of $F$ depends on the number of particles, their charges, masses, and boundary conditions.

\footnote{7} Here and in the following estimates, to be conservative, we use $F(3)$.
General deviations from $\phi^2$.—One can use the same technique to constrain other deviations from the simplest scenario: they will all contribute to the rhs of Eq. (1). Let us first focus on small deviations from $m^2 \phi^2$ coming from the shape of the potential (see for example, Refs. [13, 14]). It is straightforward to obtain the corrections to Eq. (1) for a generic $V(\phi)$ up to second order in slow-roll parameters

$$(n_s - 1) + \frac{r}{4} + \frac{11}{24}(n_s - 1)^2 = -2(\epsilon - \eta).$$

Notice that on the rhs of Eq. (8) we keep only the first nonvanishing correction.

Another kind of corrections comes from derivative interactions. Indeed, from the effective field theory point of view quantum corrections will generate higher-dimensional operators suppressed by some scale $\Lambda$. Particularly important are the operators compatible with an approximate shift symmetry for $\phi$. For example, a term of the form $(\partial \phi)^4/\Lambda^4$ in the Lagrangian corresponds to a correction to the speed of propagation of the perturbations

$$c_s^2 - 1 = 16\frac{H M_{\text{pl}}^2}{\Lambda^4}.$$  

Therefore, constraints on the speed of sound transfer into constraints on $\Lambda$. In models with $c_s < 1$, it is important to stress that $r = 16c_s$, whereas $n_s - 1$ is independent of $c_s$ (it only depends on it through $s = \dot{c}_s/Hc_s$). In the absence of cancellations, the current value for $n_s - 1$ and the detection of a high level of primordial tensor modes imply that $c_s$ cannot be much smaller than 1.

For the case of a quadratic potential, one can quantify the bounds on $c_s$ more precisely in a way that is insensitive to $N$. The correction to Eq. (1) reads

$$(n_s - 1) + \frac{r}{4} + \frac{11}{24}(n_s - 1)^2 = -s + \frac{r}{4} \left(1 - \frac{1}{c_s}\right).$$

If the total error on the lhs is of the order $10^{-3}$, $|c_s - 1|$ is constrained to be $\lesssim 3 \times 10^{-2}$. In particular, we can put a lower bound on the energy scale $\Lambda$ to be $\Lambda \gtrsim 2 \times 10^{16}$ GeV which is as high as the inflationary scale.

Another way to constrain $c_s$ is to use the standard consistency relation for the tilt of tensor modes $n_T$

$$r + 8n_T = \left(1 - \frac{1}{c_s}\right) r.$$  

This relation has the major advantage of being valid for any potential, but it is difficult to imagine we will be able to verify it with significant precision. Given that from CMB experiments it will be hard to measure $n_T$ with a precision better than $\Delta n_T \sim 0.1$, the constraint on $c_s$ is weaker than the one obtained above. However, in the very far future we might be able to constrain $r$ and $n_T$ much better by the detection of primordial gravitational waves with interferometers [15]. Optimistically, the error on $n_T$ could be as low as $5 \times 10^{-3}$ and the relation of Eq. (11) could constrain $c_s$ even better than Eq. (10).

Another possible departure from the simplest model is the presence of a subdominant component in the spectrum due to a second field. In these models (curvaton, modulated reheating, etc.) inflation is driven by the inflaton, but a second scalar field $\sigma$ is contributing to the curvature perturbation with a fraction

$$q \equiv \frac{P_\sigma}{P_\zeta + P_\zeta},$$

where $P_\zeta$ is the contribution of the field $x$ to the power spectrum of the curvature perturbation $\zeta$. The correction to Eq. (1) up to first order in slow roll is

$$(n_s - 1) + \frac{r}{4} + \frac{11}{24}(n_s - 1)^2 = q \left(\frac{r}{8} + \frac{2 V''}{3 H^2}\right).$$

Assuming that the error on the lhs of Eq. (13) is $10^{-3}$, this relation constrains $q \lesssim 0.06$.

One may consider the case in which different corrections to the rhs of Eq. (1) cancel, so that we accidentally get the same predictions as the $\phi^2$ model. In this case, one can hope to break the degeneracy by looking at the running of the power spectrum. For a quadratic potential $\alpha = -(n_s - 1)^2/2 = -r^2/32 \approx 8 \times 10^{-4}$.

Constraints on $N$.—So far, we have focused on a combination of observables that is $N$ independent. On the other hand, for a quadratic potential one will also get a good constraint on the number of e-folds. With the numbers quoted above, the best constraint will most likely come from $r$, which will give $\Delta N \approx 0.4$. This translates into an error on the reheating temperature

$$\frac{\Delta T_{\text{rh}}}{T_{\text{rh}}} \approx 1.2,$$

assuming we know the evolution after reheating. Notice that while it is easy to reduce $N$ (longer reheating, periods of matter domination or phase transitions in the late universe, large number of relativistic degrees of freedom $g_*$), the upper bound on $N$ corresponding to instantaneous reheating and conventional cosmological evolution is very robust. In some sense, it corresponds to the very simplest Universe.

What if not $\phi^2$?—All the discussion so far concentrated on $\phi^2$ inflation. If nature has chosen another monomial potential $V \propto \phi^p$, we can still build an observable which does not depend on $N$. It is easy to get

$$(n_s - 1) + \frac{2 + p}{8p} r + \frac{3p^2 + 18p - 4}{6(p + 2)^2} (n_s - 1)^2 = 0.$$  

the minimal value of $\epsilon$ that corresponds to the maximal number of e-folds.
As before we will have errors of order $10^{-3}$ on this expression\(^8\). It is straightforward to generalize Eqs. (10) and (13) to analyze the constraints on the speed of sound or the presence of a curvaton component. One can also invert Eq. (15) to find the allowed range of $p$. This reads

$$p = -\frac{2r}{8(n_s - 1) + r} - \frac{64(n_s - 1)^3}{(8(n_s - 1) + r)^2} + \frac{(n_s - 1) - 7}{24} r.$$  

For “normal” powers we will be quite convinced we have found the correct model of inflation. With the current errors the bounds on $p$ are too loose to be interesting, but this may change in the future. For example, for a linear potential the error will be $\Delta p \approx 0.06$, and this will allow discrimination of this model from $\phi^{2/3}$.

**Non-Gaussianity.**—So far our discussion has concentrated on the power spectra: what about higher-order correlation functions? As discussed above, in single-field models (independently of the potential) $r$ is suppressed by $c_s$, so that the speed of sound cannot be much smaller than 1. Therefore, the cubic operator related by symmetry to $c_s$ \(^{[16]}\) cannot give sizeable non-Gaussianities since $f_{NL}^s \sim 1/c_s^3$ (the Planck constraint \([9]\) is $c_s > 0.02$). However the second independent operator $\tilde{r}^3$ can still be large. It is straightforward to check that this situation is radiatively stable \([17]\): loops induce order-one corrections to the speed of sound. Moreover, the three-point function can be large for $c_s = 1$ if it is generated by operators with more than one derivative per field \([18]\). Another possibility is that the four-point function is large, while the bispectrum is suppressed: this can happen in a technically natural way as studied in Refs. \([19]\). Non-Gaussianities are also relevant if scalar and tensor perturbations are both produced through particle creation involving dissipative effects \([20, 21]\).

It is interesting that, if we focus on a $\phi^2$ potential, the limits on $c_s$ discussed above can be far better than what is measurable through the three-point function.

Also, in multifield models $r$ is always suppressed compared to the single-field case (by a factor of $q$ assuming no mixing). It is, thus, unlikely that perturbations are dominated by a second field. However, when the perturbations due to the second field become very non-Gaussian, they induce a large observable non-Gaussianity $f_{NL}^s \sim 10^3 q^{1/2}$, even when they are subdominant in the power spectrum \([22]\). Notice that the shape of non-Gaussianity can vary from local to equilateral if we consider general quasi-single-field models \([23, 24]\). In conclusion, non-Gaussianities remain a powerful probe of inflation.

**Conclusions.**—Any experimental result on the $(n_s, r)$ plane can be explained with a proper choice of the slow-roll parameters $\epsilon$ and $\eta$. On the other hand a particular curve on this plane stands out since it corresponds to the prediction of $V \propto \phi^2$, varying the number of e-folds $N$. Assuming data will remain compatible with this simple scenario, we studied the constraints we will be able to set on various deviations from the benchmark model.
