ABSTRACT
We present the results of a search for molecular gas emission from a star-forming galaxy at z = 4.9. The galaxy benefits from magnification of 22 ± 5 due to strong gravitational lensing by the foreground cluster MS1358+62. We target the CO(5–4) emission at a known position and redshift from existing Hubble Space Telescope/Advanced Camera for Surveys imaging and Gemini/NIFS [O II]3727 imaging spectroscopy, and obtain a tentative detection at the 4.3σ level with a flux of 0.104 ± 0.024 Jy km s$^{-1}$. From the CO line luminosity and assuming a CO-to-H$_2$ conversion factor $\alpha = 2$, we derive a gas mass $M_{\text{gas}} \sim 1.6 \times 10^9 M_\odot$. Combined with the existing data, we derive a gas fraction $M_{\text{gas}}/(M_{\text{gas}} + M_*) = 0.59^{+0.11}_{-0.06}$. The faint line flux of this galaxy highlights the difficulty of observing molecular gas in representative galaxies at this epoch, and suggests that routine detections of similar galaxies in the absence of gravitational lensing will remain challenging even with ALMA in full science operations.

Key words: galaxies: high-redshift – galaxies: star formation – gravitational lensing: strong

1. INTRODUCTION
Extensive studies of optically selected star-forming galaxies seen at the epoch of peak cosmic star formation density ($z \sim 2$) have revealed star formation rates (SFRs) of 10–100 $M_\odot$ yr$^{-1}$ and stellar masses of $10^{10}$–$10^{11} M_\odot$ (e.g., Förster Schreiber et al. 2009; Law et al. 2009; Tacconi et al. 2010; Daddi et al. 2010a). If these SFRs have been continuously maintained, then these galaxies must have undergone their first major epoch of stellar mass assembly 1–2 Gyr earlier, at $z \sim 5$, when the bulk of the star-forming population was $\sim 5 \times$ less massive (McLure et al. 2009; Stark et al. 2010).

The star formation within these galaxies is fueled by reservoirs of predominantly cold molecular hydrogen, H$_2$. Since the H$_2$ is not directly detectable, CO emission at millimeter wave-lengths has been employed to trace the cold molecular gas. However, exploring gas properties of galaxies beyond $z \sim 3$ is challenging: not only does the apparent surface brightness decrease as $(1 + z)^{-4}$, but the galaxies themselves also appear systematically smaller and intrinsically fainter, making detections of their molecular gas emission difficult.

To date, studies of molecular line emission at $z > 3$ have been limited to extreme populations such as gas-rich quasars (e.g., Walter et al. 2009) and submillimeter galaxies (SMGs; Coppin et al. 2010; Carilli et al. 2010; Riechers et al. 2011b). Detecting typical star-forming galaxies at $z > 3$ has proven difficult because the CO line luminosities are usually below the sensitivity limits of current facilities (Stanway et al. 2008; Davies et al. 2010).

However, it is still possible to study less active high-$z$ galaxies which are strongly gravitationally lensed by massive galaxy clusters. The magnification provided by gravitational lensing has enabled detections of molecular gas in a number of star-forming galaxies up to $z \sim 3$ (e.g., Baker et al. 2004; Coppin et al. 2007; Riechers et al. 2011a; Danielson et al. 2011), and more recently up to $z \sim 4$–6 (e.g., Cox et al. 2011; Combes et al. 2012). The physical properties of the interstellar medium (ISM) appear similar to those in local ultraluminous infrared galaxies (ULIRGs), with high gas fractions, high densities, and intense UV radiation fields.

Franx et al. (1997) reported the detection of a multiply imaged $z = 4.9$ galaxy which is gravitationally lensed by the massive galaxy cluster MS 1358+62. Correcting for lensing, this galaxy (hereafter MS1358-arc) appears to be representative of the star-forming population at this epoch (its lensing-corrected apparent magnitude is $I_{\text{AB}} = 24.9$, marginally brighter than the characteristic luminosity of $I_{\text{AB}} = 25.3$ at $z \sim 5$; Ouchi et al. 2004). Swinbank et al. (2009, hereafter S09) carried out a detailed study of one image of the MS1358-arc system, using optical and infrared imaging combined with integral field spectroscopy, revealing a rotating system across 2 kpc in projection, with star formation occurring in five bright clumps.

In this Letter, we report observations with the Plateau de Bure Interferometer (PdBI) to search for CO(5–4) emission in MS1358-arc. Throughout, we adopt a ΛCDM cosmology with $H_0 = 70$ km s$^{-1}$ Mpc$^{-1}$, $\Omega_\Lambda = 0.7$, and $\Omega_m = 0.3$.

2. OBSERVATIONS AND DATA REDUCTION
The MS1358+62 system is illustrated in Figure 1, with the positions of the two images of MS1358-arc marked (Table 1). We estimate the amplification of each image using the lens model of Richard et al. (2008) with lensmodel (Kneib 1993; Jullo et al. 2007), with errors accounting for the magnification gradient across the image. The combined magnification factor for Image 1 and 2 is $\mu = 22 \pm 5$.

To search for the CO(5–4) emission, we observed MS1358-arc with the IRAM PdBI (Guilloteau et al. 1992), using six antennas in D (compact) configuration. The pointing center was $\alpha_{2000} = 13:59:48.7$, $\delta_{2000} = +62:30:48.3$, and the frequency was tuned to the CO(5–4) transition (rest frame 576.2679 GHz) redshifted to 97.185 GHz (based on the
Figure 1. *Hubble Space Telescope* (HST)/ACS image of the core of MS1358+62. The squares mark the extent of the pixels in the PdBI cube used to extract the spectra shown in Figure 2. A Plateau de Bure channel map constructed from a 90 km s\(^{-1}\) window around the systemic velocity of the CO(5–4) line is shown as an inset. The PdBI synthesized beam size is indicated by the dotted ellipse in the inset. Contours are shown in ±1σ intervals, with negative contours indicated by dashed lines. The origin of the HST image coordinate system is (α\(^{2000}\), δ\(^{2000}\)) = (13h59m51.4s, +62°30′52″). (A color version of this figure is available in the online journal.)

Table 1

| Image | R.A. (J2000) | Decl. (J2000) | \(\mu\) |
|-------|--------------|---------------|--------|
| Image 1 | 13°59′48″54″ | 62°30′48″54″ | 12.4 ± 3 |
| Image 2 | 13°59′49″30″ | 62°30′45″13″ | 9.5 ± 4 |
| Image 3 | 13°59′54″746 | 62°31′5″21 | 2.9 ± 0.1 |

Note. The position of the third image is included for completeness, but is excluded from our analysis as it lies outside the primary beam.

Figure 2. CO(5–4) spectra extracted from the two images of MS1358-arc and the co-add of these spectra. The velocity scale is centered on the systemic redshift \(z = 4.9296\), and the expected position of the CO(5–4) emission line is indicated by a black dotted line. The spectra are binned into 38.6 km s\(^{-1}\) channels. The best-fit Gaussian profile to the co-added spectrum is overlaid as a guide, scaled to the relative amplifications of the two images, and the velocities of the two brightest star-forming clumps measured by S09 are indicated by vertical lines. Each image shows positive flux at the systemic redshift of MS1358-arc, but individually they are only detected at ∼3σ significance. (A color version of this figure is available in the online journal.)

[O\(\text{II}\)]-derived systemic redshift of \(z = 4.9296 ± 0.0002\) from S09. The observations were made between 2010 June 4 and 2010 June 6 with total on-source time of 10 hr, using WIDEX with a resolution of 2.5 MHz. The star MWC349 was observed as the primary flux calibrator, with the quasars 1749+096, 0923+392, and 2145+067 as secondary flux calibrators. Receiver bandpass calibration was performed against 0923+392 and 3C454.3, and 1435+638 and 1418+546 were used for phase and amplitude calibration.

The data were reduced with the g1dasa software package (Guilloteau & Lucas 2000) and resampled to a velocity resolution of 38.6 km s\(^{-1}\). The synthesized beam is a Gaussian ellipse with an FWHM size of 5″6 × 4″3 at a position angle of 111°.

The PdBI observations were centered on the two brightest images of the \(z \sim 5\) galaxy. The images are both within 6″ of the pointing center, whereas the primary beam of PdBI at 3 mm is 50″; we have therefore not corrected for primary beam attenuation, which is negligible. First, we construct a channel map from a 90 km s\(^{-1}\) window around the CO(5–4) emission line centered at the systemic redshift, and show as an inset in Figure 1, with contours at ±1σ intervals. The positions of the images within the PdBI cube are determined by aligning the cube with the *Hubble Space Telescope* image and taking the center of the corresponding pixels.

We also extract spectra from these positions and show these in Figure 2. Individually, the two images are clearly extremely faint; by comparing the \(\Delta \chi^2\) of a Gaussian profile to that of a continuum-only fit, measuring the noise over a 1200 km s\(^{-1}\) channel, the significances of the CO(5–4) emission lines in Images 1 and 2 are 3.3σ and 2.7σ, respectively. However, since they are separated by more than one beam width, we can improve the signal to noise by co-adding the spectra at the two positions using uniform weights (Figure 2); we then obtain a 1σ rms channel sensitivity of 0.4 mJy per 38.6 km s\(^{-1}\) channel. Again
comparing the $\chi^2$ of a Gaussian profile fit to that of a continuum-only fit, we use the $\Delta \chi^2$ to derive a significance level of 4.3\,$\sigma$ for the co-added CO(5–4) emission line.

Whilst the emission line centroid is extremely well matched to the best-fit redshift of the nebular emission, the line is weak, highlighting the difficulty of these observations even with long integrations. We perform a number of tests to validate the robustness of the detection. First, we check how often a detection is made when co-adding two random spectra from the original (non-co-added) cube. We generate 1000 combinations of two randomly selected pixels on the map (excluding pixels which lie within one beam of MS1358-arc), then fit a Gaussian profile to the resulting co-added spectrum and compare this to a continuum-only fit. The probability of finding an emission line of equal significance to the target from two randomly selected positions with a velocity centroid lying within $\pm 150$ km s$^{-1}$ of the redshift of MS1358-arc and a line width in the range $\sigma = 30$–250 km s$^{-1}$ is 0.05%.

The CO(5–4) emission line we measure is centered at $z = 4.9297 \pm 0.0001$ with a line flux of $0.104 \pm 0.024$ Jy km s$^{-1}$ and a full width at zero intensity of $\text{FWZI} = 150 \pm 20$ km s$^{-1}$, comparable to the velocity gradient measured across the source by S09. Error bars are obtained by fitting a Gaussian profile to the line and perturbing it in intensity, velocity, and width to obtain a $\Delta \chi^2 = 1$ error surface, using a Monte Carlo routine with $10^5$ realizations centered on the best fit.

We also construct a co-added channel map from the PdBI cube by extracting regions centered on the two images and co-adding them. The co-added cube is then spatially convolved with the PdBI beam, and spectrally convolved with a Gaussian with FWHM = 100 km s$^{-1}$. We estimate the noise at each spatial position using the off-line spectrum at that position, and divide
the signal in the on-line slice of the convolved datacube by this noise map to construct a signal-to-noise map, shown in Figure 3. We find that 99.95% of the pixels have lower signal to noise than the target. This is equivalent to a detection significance of 3.5σ.

In the following analysis, we treat the line flux as 0.104 ± 0.024 Jy km s⁻¹, but discuss the implications of treating it as an upper limit in Section 4.

3. RESULTS, ANALYSIS, AND DISCUSSION

3.1. CO Dynamics, Luminosity, and Molecular Gas Mass

Using the combined spectrum of Images 1 and 2, we first estimate the line luminosity and gas mass. Following Solomon & Vanden Bout (2005), the line luminosity is \( L'_{\text{CO}(5–4)} = (3.6 ± 0.8) \times 10^8 \) K km s⁻¹ pc². Adopting a magnification factor of \( \mu = 22 ± 5 \), this indicates an intrinsic \( L_{\text{CO}(5–4)} = (1.6 ± 0.5) \times 10^8 \) K km s⁻¹ pc².

To convert this CO(5–4) luminosity to a total molecular gas mass, we must first estimate the corresponding CO(1–0) line luminosity. We therefore exploit recent observations of \( z = 2–4 \) galaxies, where the ratio \( L'_{\text{CO}(5–4)}/L_{\text{CO}(1–0)} \) has been measured directly, e.g., \( L_{\text{CO}(5–4)}/L_{\text{CO}(1–0)} = 0.35 ± 0.02 \) for SMM J2135 (Danielson et al. 2011) or 0.32 ± 0.05 for a sample of SMGs (Bothwell et al. 2012). We adopt the latter value and applying it to MS1358-arc, we estimate \( L'_{\text{CO}(1–0)} = (5.0 ± 1.7) \times 10^8 \) K km s⁻¹ pc². If we instead assumed \( L_{\text{CO}(5–4)}/L_{\text{CO}(1–0)} \) from either the Antennae, 0.2 (Zhu et al. 2003); NGC 253, 0.7 (Bayet et al. 2004); or M82, 0.7 (Weiß et al. 2005), this estimate would vary by a factor of two in either direction and so we adopt this as the likely systematic uncertainty in our estimate.

To derive the molecular gas mass \( M_{\text{gas}} \) from \( L_{\text{CO}(1–0)} \), we assume \( M_{\text{gas}} = \alpha L_{\text{CO}(1–0)} \), where \( \alpha \) is the coefficient relating the CO to H₂+He gas mass. We can derive an absolute lower limit for \( \alpha \) by assuming that the molecular gas is enriched to solar metallicity and is optically thin to CO radiation. From Ivison et al. (2010), we have \( \alpha \geq 0.7 \), which is consistent with the value \( \alpha = 0.8 \) applied to local (U)LIRGs (Solomon & Vanden Bout 2005). However, recent studies of high-z star-forming galaxies have suggested that \( \alpha \sim 2 \) may be a more appropriate conversion factor (e.g., Danielson et al. 2011; Ivison et al. 2011). Adopting this value, we find \( M_{\text{gas}} = 5.5 \pm 0.3 \times 10^9 \) M⊙, where we conservatively estimate a factor of two times uncertainty in \( \alpha \), comparable to the uncertainty in \( L_{\text{CO}(5–4)}/L_{\text{CO}(1–0)} \).

Combining our gas mass estimate with the stellar mass \( M_* = 7 ± 2 \times 10^9 \) M⊙ derived by S09, we obtain a total baryonic mass of \( M_{\text{baryon}} = M_* + M_{\text{gas}} = 1.7 ± 1 \times 10^10 \) M⊙. This is consistent with the dynamical mass within 2 kpc derived by S09 of \( M_{\text{dyn}} = 3 ± 1 \times 10^10 \) csc²(μ) (M⊙), if the inclination is \( i \geq 45° \).

The gas fraction \( f_{\text{gas}} = M_{\text{gas}}/(M_{\text{gas}} + M_*) \) is typically <10% in local large spiral galaxies (Young & Scoville 1991), or ~33% in local ULIRGs (Solomon et al. 1997). Other studies of molecular gas in high-redshift galaxies are beginning to find a trend for higher gas fractions at higher redshifts (Tacconi et al. 2010; Geach et al. 2011), which is in line with expectations from hydrodynamical simulations (Crain et al. 2009). For MS1358-arc, we find \( f_{\text{gas}} = 0.59_{-0.04}^{+0.01} \), with a systematic uncertainty of ~±0.20 due to \( \alpha \) and \( L_{\text{CO}(5–4)}/L_{\text{CO}(1–0)} \).

In Figure 4, we compare the gas fraction of MS1358-arc to samples at lower redshift (see also Geach et al. 2011). The sample size is currently too small to draw any firm conclusions, and there are of course significant selection effects involved. We therefore caution that there are limits to the extent of any physical interpretation of this result, although it clearly motivates a uniformly selected survey of the gas properties of high-redshift star-forming galaxies.

We can also use the dynamics of the [O II] emission to test whether the molecular gas is colocated with the star formation. In Figure 2, we overplot the redshifts of the two brightest star-forming knots, which are located at ±150 km s⁻¹ from the dynamical center. Hence, if the CO gas traced the [O II] emission, we would expect a FWZI of ~300 km s⁻¹, higher than the observed line width. This may indicate that the CO emission is associated with the dynamical center of the galaxy rather than being concentrated in the star-forming regions or associated with the outflowing Lyα and UV–ISM lines (S09).

3.2. Gas Depletion Timescales

S09 derived an SFR of \( 42 ± 8 \) M⊙ yr⁻¹ using the Kennicutt (1998) conversion from [O II] luminosity to SFR. We note that this conversion is consistent with the empirical correction to this calibration of Gilbank et al. (2010), which accounts for the metallicity dependence of the [O II]-derived SFR.

If MS1358-arc has sustained this SFR continuously, then the time taken to build up the current stellar mass of \( 7 ± 2 \times 10^9 \) M⊙ is just \( t_{\text{build}} \sim 17 \) Myr (consistent with the age and star formation history used to derive the stellar mass). This suggests that we may be seeing this galaxy in its first epoch of star formation. If this SFR is maintained at a constant level, the gas supply of \( 1 \times 10^9 \) M⊙ will be exhausted within ~24 Myr, which would place the galaxy ~40% of the way through its starburst.
compared to that inferred indirectly for the LBG population at $z = 4$–6, which has implied starburst lifetimes of $\lesssim 500$ Myr (Stark et al. 2009), but is consistent with the lifetime of the starburst-triggered “Lyman Break Galaxy phase” predicted by semi-analytic models (Gonzalez et al. 2011).

Finally, we note that the ratio between far-infrared luminosity and molecular gas mass, $L_{\text{FIR}}/M_{\text{H}_2}$, gives the star formation efficiency (SFE), relating the ongoing star formation to the available molecular gas.

Knudsen et al. (2008) obtained an upper limit on the 850 $\mu$m flux of MS1358-arc of $S_{850} < 4.8$ mJy which, accounting for the lensing magnification and using the $S_{850}$-$L_{\text{FIR}}$ calibration of Neri et al. (2003), suggests a far-infrared (FIR) luminosity $L_{\text{FIR}} < 3.5 \times 10^{11} L_{\odot}$ (we note that if we assume that the FIR flux is re-emitted light from dust-obscured star formation and apply the Kennicutt (1998) relation to our [O II]-derived SFR, we obtain $L_{\text{FIR}} = (2.3 \pm 0.9) \times 10^{11} L_{\odot}$, which is consistent with this upper limit). We thus obtain SFE $\lesssim 2.40 L_{\odot}/M_{\odot}$. For comparison, the median SFE in local ULIRGs is $49 \pm 6 L_{\odot}/M_{\odot}$ when corrected to $\alpha = 2$, although this rises to $172 \pm 23 L_{\odot}/M_{\odot}$ if $\alpha = 0.8$, which is the factor commonly applied to ULIRGs (Sanders et al. 1991), while SMGs give SFE $\sim 55^{+20}_{-15} L_{\odot}/M_{\odot}$ for $\alpha = 2$ (Bothwell et al. 2012). Our upper limit is consistent with these values.

4. CONCLUSIONS

We have used the IRAM PdBI to search for the CO(5–4) emission in a $z = 4.9296$ galaxy lensed by the foreground cluster MS1358+62. We were able to observe two images of the galaxy simultaneously, with a total magnification factor of $22 \pm 5 \times$. We measure a line flux of $0.104 \pm 0.024$ Jy km s$^{-1}$ at the position of the galaxy, yielding a detection at $3.5 \sigma$.–4.3 $\sigma$.

The molecular gas shows a relatively narrow velocity range around the systemic redshift, unlike the [O II] emission, which mainly arises from two clumps in the galaxy at $\pm 150$ km s$^{-1}$. This may suggest that the gas is more centrally concentrated than the star formation.

We derive a total gas mass $M_{\text{gas}} = 1.7 \times 10^9 M_{\odot}$, suggesting that this galaxy has a gas fraction $f_{\text{gas}} = 0.59^{0.11}_{0.06}$, with a systematic uncertainty of $\sim 0.20$ due to $\alpha$ and $L_{\text{CO}(5-4)}/L_{\text{CO}(1-0)}$, which is similar to the most gas-rich galaxies at $z \sim 2$. This could imply that gas fractions do not continue to rise significantly beyond $z \sim 2$, though a larger sample is clearly needed to draw any conclusions.

Finally, given the tentative nature of the detection, we consider the implications of treating the measured flux as a $4\sigma$ upper limit. In this case, the resulting gas mass $M_{\text{gas}} < 1 \times 10^9 M_{\odot}$ would be lower than expected given the stellar and dynamical masses derived by S09, and the gas fraction would be $f_{\text{gas}} < 0.6$. This would also imply a gas depletion timescale of $<24$ Myr, placing the galaxy more than 40% of the way through a short starburst.

Our observations highlight the difficulty of measuring gas properties of “representative” star-forming galaxies at $z \sim 5$, an era when many of today’s massive galaxies may be undergoing their first major episode of star formation. Probing their basic properties—their stellar and gas content and relation to star formation—will provide important physical quantities which galaxy formation models must reproduce.
