Abstract

The likelihood of development of degenerative joint disease (DJD) of the temporomandibular joint (TMJ) is related to the integrity of the TMJ disc. Predilection for mechanical failure of the TMJ disc may reflect inter-individual differences in TMJ loads. Nine females and eight males in each of normal TMJ disc position and bilateral disc displacement diagnostic groups consented to participate in our study. Disc position was determined by bilateral magnetic resonance images of the joints. Three-dimensional (3D) anatomical geometry of each subject was used in a validated computer-assisted numerical model to calculate ipsilateral and contralateral TMJ loads for a range of biting positions (incisor, canine, molar) and angles (1-13). Each TMJ load was a resultant vector at the anterosuperior-most mediolateral midpoint on the condyle and characterized in terms of magnitude and 3D orientation. Analysis of variance (ANOVA) was used to test for effects of biting position and angle on TMJ loads. Mean TMJ loads in subjects with disc displacement were 9.5-69% higher than in subjects with normal disc position. During canine biting, TMJ loads in subjects with disc displacement were 43% (ipsilateral condyle, p=0.029) and 49% (contralateral condyle, p=0.015) higher on average than in subjects with normal disc position. Biting angle effects showed that laterally directed forces on the dentition produced ipsilateral joint loads, which on average were 69% higher (p=0.002) compared to individuals with normal TMJ disc position. The data reported here describe large differences in TMJ loads between individuals with disc displacement and normal disc position. The results support future investigations of inter-individual differences in joint mechanics as a variable in the development of DJD of the TMJ.

Introduction

Degenerative changes of the human temporomandibular joint (TMJ) are evident in 3-29% of the population aged 19-40 years.1 Although degenerative joint disease (DJD) is common in the human TMJ, the pathomechanics are poorly understood. The mean age of onset of DJD of the human TMJ is between 25 and 35 years20 and approximately 20 years earlier than reported for the hip.21,22 Therapeutic interventions to ameliorate the effects of DJD in the TMJ, like other synovial joints, have not been predictably successful.23 The intra-articular disc is the main mechanism of load distribution and lubrication in the TMJ.24 Although the high prevalence of disc displacement in otherwise asymptomatic adults has led some researchers to propose that it is a non-pathological variation of anatomy,25 disc displacement is absent mostly in the young, increases with time through adolescence and early adulthood, and thus precedes the precarious time-line of DJD in the TMJ.25-27 It has been postulated that the propensity to develop DJD of the TMJ depends on the health of the disc,27 which is anisotropic with respect to mechanical fatigue.28 The objective of our study was to use a numerical modeling approach25-27 to test the hypothesis that TMJ loads during static biting are larger in subjects with TMJ disc displacement compared to subjects with normal disc position.

Materials and Methods

Thirty-four subjects gave informed consent to participate. The study protocol was approved by Institutional Review Boards. Subjects had generally intact dentitions, and did not report or exhibit postranarial DJD, orofacial pain, gross asymmetries in craniomandibular anatomy as determined by examination, and were not pregnant as determined by medical history. Diagnostic classification was established by a clinical examiner using research diagnostic criteria for temporomandibular disorders28 and a radiologist using magnetic resonance imaging and three-dimensional (3D) computed tomography.29 The subjects, 18 females and 16 males, were divided evenly into two diagnostic groups (Table 1). Mean ages (SD) were 35 (14) and 34 (15) years for disc displacement and normal disc position groups, respectively. A geometry file was created for each subject that described positions of the mandibular condyles, teeth, and five pairs of masticatory muscles (masseter, anterior temporalis, medial pterygoid, lateral pterygoid, anterior digastric), determined from standardized lateral and posterior anterior cephalograms according to a 3D coordinate system29 (Figure 1). Geometry files

Table 1. Subjects in two diagnostic groups.

| Gender | Number of subjects with normal disc position bilaterally | Number of subjects with disc displacement (II) according to KCDC/TMD categories (a, b, c): |
|--------|----------------------------------------------------------|--------------------------------------------------------------------------------------|
|        | Ila | Ilb | Ilc |                               |                               |                               |
| Female | 9   | 6   | 1   | 2 |                               |                               |                               |
| Male   | 8   | 6   | 1   | 1 |                               |                               |                               |

Where: Ila = disc displacement with reduction, Ilb = disc displacement without reduction with limited opening, Ilc = disc displacement without reduction without limited opening (more complete criteria and definitions have been published previously29).
were used in a previously described numerical model,\(^3\) first to validate the accuracy of the model in predicting data in each subject, and then to investigate inter-group differences in magnitudes of TMJ loads. Model-predicted ipsilateral and contralateral TMJ loads for a given static mandibular loading situation were resultant vectors at the anterosuperior-most mediolateral midpoint on the corresponding condyle and characterized in terms of magnitude and 3D orientation.

Model validation was determined by the ability to predict right and/or left sagittal plane projections of the TMJ stress-field trajectory in each subject\(^3\) during symmetrical protrusion and retraction of the mandible. That is, model-predicted orientations of TMJ loads were used as described previously and compared to individual-specific jaw tracking data measured in \textit{vivo}.\(^2\) Accuracy between model-predicted and measured data was deemed to be acceptable based on average errors of 16\% (Iwasaki \textit{et al.}, personal communication). Then the validated model was used to predict magnitudes of TMJ forces per unit biting force (BF) using an objective function of minimization of muscle effort (MME).\(^2\) The MME model calculated joint forces for biting on incisor, canine, and molar teeth, at a variety of angles (Tables 2, 3). Data were pooled and averaged by group. Analysis of variance (ANOVA) was used to test for significant differences between groups for magnitudes of TMJ loads during biting on incisors, canines, and molars at 13 angles.

**Results**

Among all biting positions and angles, mean predicted TMJ loads were 9.5-69\% higher in subjects with disc displacement compared to subjects with normal disc position. The highest mean predicted TMJ loads occurred during canine biting in subjects with disc displacement (Table 2), where mean contralateral joint loads were 138\% of the BF. During canine biting, between-group differences in mean TMJ loads of 43\% (ipsilateral, \(p=0.029\)) and 49\% (contralateral, \(p=0.015\)) were statistically significant (Figure 2).

With respect to the effects of biting angle, vertical and laterally-directed BF produced significant differences in joint loads between the two diagnostic groups. In all cases, ipsilateral and contralateral joint loads in the subjects with disc displacement were higher, with statistically significant differences (all \(p<0.05\)) occurring during vertical (biting angle 1), laterally-directed (biting angles 2, 3), and anterolaterally-directed biting (biting angle 12; Figure 3; Table 3 a,b).
The data presented here are the first to imply that subjects with TMJ disc displacement have higher joint loads compared to subjects with normal disc position. During daily activities, subjects with disc displacement were capable of producing TMJ loads >60% higher than control subjects. TMJ loads predicted by validated computer modeling showed intergroup differences and suggest that inter-individual differences in joint mechanics are potential variables in DJD of the TMJ.

The numerical modeling approach has limitations that have been discussed in detail previously.28 One of these limitations is the simplified representation of joint and muscle forces. The model predicts magnitudes of these forces and also the direction of joint forces based on individual-specific anatomical data that include the position and direction of masticatory muscle forces. The area of joint loading in the individual is an important variable and should be investigated in future studies; for example, through dynamic stereometry.31 Furthermore, the muscles of mastication are multi-pennate muscles and, theoretically, each anatomical portion of a muscle can be represented by a vector. These vectors can be summed to produce a single unit vector. Variation in the direction of this unit vector depends on whether or not discrete areas of a muscle can be differentially activated. Contrary to reported conclusions, documented data for the masseter and temporalis muscles fail to show discrete differential activation of portions of muscles except with cortical feedback. That is, for the masseter muscle no single portion was solely active for a variety of tasks performed35 and near absence of differential activation was shown for most biting loads.36 The posterior deep portion behaved most differently from the rest of the masseter muscle, but behaved similarly to the neighboring temporalis muscle,37 which may indicate cross-talk from the latter muscle. Similarly all portions of the temporalis muscle were active during biting tasks and extremes of unit vector orientation were relatively inconsequential (<10°).37 These findings sup-

Discussion

The data presented here are the first to imply that subjects with TMJ disc displacement have higher joint loads compared to subjects with normal disc position. During daily activities, subjects with disc displacement were capable of producing TMJ loads >60% higher than control subjects. TMJ loads predicted by validated computer modeling showed intergroup differences and suggest that inter-individual differences in joint mechanics are potential variables in DJD of the TMJ.

The numerical modeling approach has limitations that have been discussed in detail previously.28 One of these limitations is the simplified representation of joint and muscle forces. The model predicts magnitudes of these forces and also the direction of joint forces based on individual-specific anatomical data that include the position and direction of masticatory muscle forces. The area of joint loading in the individual is an important variable and should be investigated in future studies; for example, through dynamic stereometry.31 Furthermore, the muscles of mastication are multi-pennate muscles and, theoretically, each anatomical portion of a muscle can be represented by a vector. These vectors can be summed to produce a single unit vector. Variation in the direction of this unit vector depends on whether or not discrete areas of a muscle can be differentially activated. Contrary to reported conclusions, documented data for the masseter and temporalis muscles fail to show discrete differential activation of portions of muscles except with cortical feedback. That is, for the masseter muscle no single portion was solely active for a variety of tasks performed35 and near absence of differential activation was shown for most biting loads.36 The posterior deep portion behaved most differently from the rest of the masseter muscle, but behaved similarly to the neighboring temporalis muscle,37 which may indicate cross-talk from the latter muscle. Similarly all portions of the temporalis muscle were active during biting tasks and extremes of unit vector orientation were relatively inconsequential (<10°).37 These findings sup-
port the use of a unit vector as a reasonable first approximation of the force vector. Another limitation is the 2D validation currently used; however, capabilities for 3D validation using dynamic stereometry should be possible in future. In addition, further validation of muscle force magnitudes during modeled jaw tasks using EMG data recorded in vivo during similar tasks should be carried out in future.

Nevertheless, currently there are no other acceptable means known, besides the validated numerical modeling approach, to determine individual-specific TMJ forces during static or dynamic loading of the jaws. Additional future work should focus on diagnostic group differences in intracapsular mechanics and frequency of loading as variables associated with fatigue failure of the TMJ articulating tissues.
