We study a fully on-fiber optomechanical cavity and characterize its performance as a sensor. The cavity is formed by patterning a suspended metallic mirror near the tip of an optical fiber and by introducing a static reflector inside the fiber. Optically induced self-excited oscillation (SEO) is observed above a threshold value of the injected laser power. The SEO phase can be synchronized by periodically modulating the optical power that is injected into the cavity. Noise properties of the system in the region of synchronization are investigated. Moreover, the spectrum is measured near different values of the modulation frequency, at which phase locking occurs. A universal behavior is revealed in the transition between the regions of phase locked and free running SEO.

I. INTRODUCTION

Resonant detection is a widely employed technique in a variety of applications. A detector belonging to this class typically consists of a resonator, which is characterized by an angular resonance frequency $\omega_0$ and characteristic damping rate $\gamma_0$. Detection is achieved by coupling a physical parameter of interest, denoted here as $q$, to the resonator in such a way that $\omega_0$ becomes $q$ dependent. The sensitivity of the detection scheme that is employed for monitoring the parameter of interest $q$ can be characterized by the minimum detectable change in $q$, denoted as $\delta q$. For small changes, $\delta q$ is related to the minimum detectable relative change in the frequency $\sigma_0 = \delta \omega_0/\omega_0$ by the relation

$$
\delta q = |\partial \omega_0/\partial q|^{-1} \omega_0 \sigma_0.
$$

The dimensionless parameter $\sigma_0$, in turn, typically depends on the noises affecting the resonator and on the averaging time $t_a$ of the measurement.

A commonly employed detection scheme is based on externally driving the resonator with a monochromatic force at a frequency close to the resonance frequency and monitoring the response using homodyne detection. For this case the normalized minimum detectable change in the frequency is found to be given by

$$
\sigma_0 = \left(\frac{2\gamma_0 k_B T_{\text{eff}}}{U_0 \omega_0^2 t_a}\right)^{1/2},
$$

(1)

$k_B$ is the Boltzmann’s constant, $T_{\text{eff}}$ is the noise effective temperature and $U_0$ is the energy stored in the externally driven resonator in steady state. Note that Eq. (1) is derived by assuming that the response of the resonator is linear and by assuming the classical limit, i.e. $k_B T_{\text{eff}} \gg \hbar \omega_0$, where $\hbar$ is Planck’s constant. The generalization of Eq. (1) for the case of nonlinear response is discussed in Ref. [2]. Note that other contributions to $\sigma_0$ (e.g. instrumental noise) are not analyzed in this paper.

In the just mentioned scheme the resonator is driven into a so-called state of forced oscillation (FO) by applying a fixed periodic external force. Alternatively, in some cases back-reaction effects can be exploited for generating a so-called state of self-excited oscillation (SEO) [3-6]. In this paper we study SEO in an on-fiber optomechanical cavity device (see Fig. 1), which is formed between a fiber Bragg grating (FBG) mirror, serving as a static reflector, and a vibrating mirror fabricated on a mechanical resonator next to the tip of the single mode optical fiber. The movable mirror can be driven into the SEO state by injecting a monochromatic laser light into the fiber. The SEO occurs via bolometric feedback effects. Further, by periodically modulating the laser intensity it is possible to lock the phase of SEO to a rational fraction of the modulation frequency.

Driving an on-fiber optomechanical cavity into the state of SEO is easier in comparison with the case of FO, which requires the fabrication of additional elements near the tip of the fiber that need to be electrically wired. In contrast, SEO can be induced by optical excitation only. In this paper, we study the performance of the device as a sensor in the regime of SEO, both with and without synchronization, and compare the results to the case of FO [see Eq. (1)]. We find that synchronization gives rise to a suppression in phase noise, which in turn allows a sensitivity enhancement.

Optomechanical cavities [7, 13] are widely employed for various sensing [3-6] and photonics [14, 20] applications. Such systems may allow experimental study of the crossover between classical to quantum realms [21]. The effect of radiation pressure typically governs the optomechanical coupling (i.e. the coupling between the electromagnetic cavity and the mechanical resonator that serves as a movable mirror) when the finesse of the optical cavity is sufficiently high [3, 11, 22, 29], whereas, bolometric effects can contribute to the optomechanical coupling when optical absorption by the vibrating mirror is significant [11, 26, 33]. Generally, bolometric effects are dominant in systems comprising of relatively large mirrors, in
which the thermal relaxation rate is comparable to the mechanical resonance frequency \[\frac{\omega_0}{2\gamma_0} = 3800\] and the cavity has finesse \[\beta = 2.1\]. The reflected light intensity is measured using a photodetector (PD), which is connected to both a spectrum analyzer and an oscilloscope (not shown in the sketch). (b) Electron micrograph of the suspended micromechanical mirror, whose mass is \[m = 1.1 \times 10^{-12}\] kg.

II. EXPERIMENTAL SETUP

The optomechanical cavity, which is schematically shown in Fig. (a), was fabricated on the flat polished tip of a single mode fused silica optical fiber with outer diameter of 126 \(\mu m\) (Corning SMF-28 operating at wavelength band around 1550 nm) held in a zirconia ferrule. A 10 nm thick chromium layer and a 200 nm gold layer were successively deposited by thermal evaporation. The bilayer was directly patterned by a focused ion beam to the desired mirror shape (20 \(\mu m\) wide doubly clamped beam). Finally, the mirror was released by etching approximately 12 \(\mu m\) of the underlying silica in 7% HF acid (90 min etch time at room temperature). The suspended mirror remained supported by the zirconia ferrule, which is resistant to HF.

The static mirror of the optomechanical cavity was provided by a FBG mirror \[36\] (made using a standard phase mask technique \[45\] with grating period of 0.527 \(\mu m\) and length \(\approx 8\) mm) having reflectivity band of 0.4 nm full width at half maximum centered at \(\lambda_0 = 1545\) nm. The length of the optical cavity was \(l \approx 10\) mm, providing a free spectral range of \(\Delta \lambda = \lambda_0^2/2n_{\text{eff}}\lambda \approx 80\) pm (where \(n_{\text{eff}} = 1.468\) is the effective refraction index for SMF-28).

Monochromatic light was injected into the fiber bearing the cavity on its tip from a laser source with an adjustable output wavelength \(\lambda\) and power level \(P_0\). The laser was connected through an optical circulator, that allowed the measurement of the reflected light intensity \(P_R\) by a fast responding photodetector [see Fig. (a)]. The detected signal was analyzed by an oscilloscope and a spectrum analyzer. The experiments were performed in vacuum (at residual pressure below 0.01 Pa) at a base temperature of 77 K.

The optically-induced SEO in our device is attributed to the bolometric optomechanical coupling between the optical mode and the mechanical resonator \[36, 37\]. While the phase of SEO randomly diffuses in time when the laser power that is injected into the cavity is kept constant, phase locking \[40, 51\] may occur when the laser power is periodically modulated in time. Such locking results in entrainment \[52\], i.e. synchronization \[53, 54\] between the SEO and the external modulation \[55\].

III. EVOLUTION EQUATION

In the limit of small displacement the dynamics of the system can be approximately described using a first order evolution equation given by \[57, 58\]

\[
\dot{A} + (\Gamma_{\text{eff}} + i\Omega_{\text{eff}})A = \xi(t) + \vartheta(t).
\]

The complex amplitude \(A\) is related to the mechanical displacement \(x(t)\) by \(x(t) = x_0 + 2\Re[A]\), where \(x_0\) is an optically-induced static displacement. Overdot denotes a derivative with respect to time \(t\). To lowest nonvanishing order in \(|A|^2\) the damping rate \(\Gamma_{\text{eff}}\) and the angular resonance frequency \(\Omega_{\text{eff}}\) are given by \(\Gamma_{\text{eff}} = \Gamma_0 + \Gamma_2 |A|^2\) and \(\Omega_{\text{eff}} = \Omega_0 + \Omega_2 |A|^2\). The term \(\xi(t)\) represents the effective force that is generated due to the laser power modulation. The fluctuating term \(\vartheta(t) = \vartheta_x(t) + i\vartheta_y(t)\), where both \(\vartheta_x\) and \(\vartheta_y\) are real, represents white noise \[57, 58\] and the following is assumed to hold: \(\langle \vartheta_x(t) \vartheta_x(t') \rangle = \langle \vartheta_y(t) \vartheta_y(t') \rangle = 2\Theta \delta(t - t')\) and \(\langle \vartheta_x(t) \vartheta_y(t') \rangle = 0\), where \(\Theta = \gamma_0 k_B T_{\text{eff}}/4m\omega_0^3\), \(\gamma_0\) and \(\omega_0\) are, respectively, the intrinsic damping rate and angular frequency of the resonator, \(m\) is its mass, \(k_B\) is the Boltzmann’s constant and \(T_{\text{eff}}\) is the effective noise temperature. Expressions for the coefficients \(x_0, \Gamma_0, \Gamma_2, \Omega_0\) and \(\Omega_2\), which all depend on the properties of the optical cavity and on the laser wavelength and power, are given in appendix A.
IV. RESONANCE DETECTION WITH SEO

In the absence of laser modulation, i.e. when \( \xi(t) = 0 \), the equation of motion (2) describes a van der Pol oscillator [47]. Consider the case where \( \Gamma_2 > 0 \), for which a supercritical Hopf bifurcation occurs when the linear damping coefficient \( \Gamma_0 \) vanishes. Above threshold, i.e. when \( \Gamma_0 \) becomes negative, the amplitude \( A_r \) of SEO is given by \( r_0 = -\Gamma_0/\Gamma_2 \) and the angular frequency \( \Omega_H \) of SEO by \( \Omega_H = \Omega_{\text{eff}}(r_0) \).

The method of resonance detection can be implemented in the regime of SEO. The normalized minimum detectable change in the frequency \( \sigma_\omega \) in this regime has been evaluated in [50], and it was found to be given by

\[
\sigma_\omega = \sigma_{\omega,0} \left( 1 + \frac{\zeta_0^2}{4 |\Gamma_0| \Gamma_2} \right)^{1/2},
\]

where \( \zeta_0 = d\Omega_{\text{eff}}/d|A| \). The above result indicates that for the same value of the stored energy \( U_0 \) the smallest detectable change \( \delta_\omega \) in the measured parameter \( q \) is \( (1 + c_0^2/4 |\Gamma_0| \Gamma_2)^{1/2} \) larger for the current case of SEO in comparison with the case of FO [see Eq. (4)]. The reduced sensitivity is attributed to the dependence of \( \Omega_{\text{eff}} \) on the amplitude \( |A| \) of oscillation, which gives rise to elevated phase noise. Recall that in the regime of SEO, in which no periodic driving is applied, the phase of oscillation is not externally dictated, and consequently it becomes more susceptible to noise. For the device under study in this work the degradation factor is given by \( (1 + c_0^2/4 |\Gamma_0| \Gamma_2)^{1/2} \approx 10 \).

V. SYNCHRONIZATION

In the regime of SEO phase noise can be suppressed by modulating the injected laser power at an angular frequency \( \omega_d \) close to the angular frequency \( \Omega_{\text{eff}} \). When fluctuations are dominated by phase noise Eq. (2) can be simplified by disregarding fluctuations in the amplitude \( |A| \) (i.e. by assuming that \( |A| = r_0 \)). In this approach one finds that the relative phase \( \gamma \) between mechanical oscillation and the applied modulation evolves in time according to [see Eq. (B14)]

\[
\frac{d\gamma}{dt} + \sin \gamma = i_b + i_n,
\]

where \( i_b = (\omega_d - \Omega_{\text{eff}})/\omega_a \) is a normalized detuning, \( \tau = \omega_d t \) is a dimensionless time variable and \( \omega_a \) is the modulation amplitude. The term \( i_n \) represents white noise having a vanishing expectation value \( \langle i_n \rangle = 0 \) and autocorrelation function \( \langle i_n(\tau) i_n(\tau') \rangle = \left( 2\Omega/\omega_a r_0^2 \right) \delta (\tau - \tau') \) [see Eq. (B13)].

In the region of synchronization, in which \( |i_n| \leq 1 \), Eq. (4) has a stationary solution given by \( \gamma = \sin^{-1} i_b \), whereas \( \gamma \) becomes time dependent when \( |i_n| > 1 \). In that region and when noise is disregarded the time evolution of \( \gamma(\tau) \), which is given by Eq. (B15), is a periodic function of \( \tau \) with a period given by \( T_J = 2\pi/\sqrt{\gamma^2 - 1} \) [see Eq. (B10)]. The Fourier series expansion of \( d\gamma/d\tau \) is given by Eqs. (B24) and (B25). The periodic time evolution of the relative phase \( \gamma \) gives rise to sidebands in the spectrum at the angular frequencies \( \omega_d + n\omega_a \), where \( n \) is an integer and the sideband spacing \( \omega_s \) is given by \( \omega_s = 2\pi\omega_a/T_J = \sqrt{(\omega_d - \Omega_{\text{eff}})^2 - \omega_a^2} \).

The equation of motion (4) indicates that the dynamics of the relative phase \( \gamma \) is governed by a potential \( U_b(\gamma) = -\cos \gamma - i_b \gamma \) having the shape of a tilted washboard. The shape of the barriers separating local minima points of \( U_b(\gamma) \) (when \( |i_n| < 1 \)) can be controlled by adjusting the frequency detuning \( \omega_d - \Omega_{\text{eff}} \) and modulation amplitude \( \omega_a \). The highly nonlinear response of the system near to onset point of synchronization can be exploited for some sensing applications. Near synchronization threshold, i.e. when \( |i_n| \lesssim 1 \), noise may give rise to phase slip events (i.e. transitions between neighboring potential wells). The average rate of noise-induced events can be estimated using the Kramers formula [60, 61]. Note that an equation of motion similar to (4) governs the dynamics of a current-biased Josephson junction in the so-called overdamped regime [62]. The effect of the noise term \( i_n \) on voltage fluctuations across a Josephson junction in the quantum regime has been investigated in [63, 64].

VI. SA MEASUREMENTS

The measured power spectrum of the photodetector signal is plotted in Fig. (2) as a function of \( \omega_d - \Omega_{\text{eff}} \)/\( \Omega_{\text{eff}} = i_b \omega_a/\Omega_{\text{eff}} \). In the absence of power laser modulation the frequency of SEO is given by \( \Omega_{\text{eff}}/2\pi = 236.4 \text{ kHz} \). As can be seen from Fig. (2), the region \( (\omega_d - \Omega_{\text{eff}})/\Omega_{\text{eff}} \leq 2.1 \times 10^{-4} \) synchronization occurs, and thus \( \omega_d/2\pi \approx 49.6 \text{ Hz} \) for this measurement. The above-discussed side bands are clearly visible in the region \( |(\omega_d - \Omega_{\text{eff}})/\Omega_{\text{eff}}| > \omega_a/\Omega_{\text{eff}} \), i.e. when \( |i_n| > 1 \). The theoretically calculated power spectrum is presented in Fig. (2) for comparison. The amplitudes of the sidebands are determined using the Fourier series expansion [see Eqs. (B24) and (B25)]. Good agreement between data and theory is found.

For the data presented in Fig. (2), synchronization occurs when \( \omega_d/\Omega_{\text{eff}} \approx 1 \). Similar synchronization is observed when the ratio \( \omega_d/\Omega_{\text{eff}} \) is tuned close to other rational values [42, 43]. As an example, the measured power spectrum for the case where \( \omega_d/\Omega_{\text{eff}} \approx 1/2 \) is shown in Fig. (3). As can be seen from the comparison with Fig. (2), the results are qualitatively similar. Not shown here, but very similar behaviors were also experimentally observed at other ratios including \( \omega_d/\Omega_{\text{eff}} \approx 1/3, 2/3, 1/4, 3/4, 1/5, 2/5, 3/5 \) and 4/5. This highlights universal aspects of the phase-locking phenomenon when the drive frequency approximately matches a rational multiple of the natural self-oscillation.
frequency.

Phase locking near rational values of the ratio $\omega_b/\Omega_{\text{eff}}$ is qualitatively discussed in appendix C. It is found that just outside the locking regime the frequency of oscillation undergoes a transition from a value dictated by the externally applied modulation to the value corresponding to free running SEO. Moreover, this transition is expected to obey a “square root law” for both integer and fractional values of the ratio $\omega_b/\Omega_{\text{eff}}$. That is, the unlocking occurs continuously, with the deviation between the fractional values of the ratio $\frac{\omega_b}{\Omega_{\text{eff}}}$ and the dimensionless laser modulation amplitude to 0.025.

In both plots synchronization occurs when $|i_b| < 1$ and sidebands are observed when $|i_b| > 1$.

FIG. 2: Power spectrum (in dB units) vs. detuning. (a) The measured power spectrum as a function of $(\omega_d - \Omega_{\text{eff}}) / \Omega_{\text{eff}}$, where $\Omega_{\text{eff}}/2\pi = 236.4$ kHz. In this measurement the average laser power is set to $P_L = 12$ mW, the wavelength to $\lambda = 1545.498$ nm and the dimensionless laser modulation amplitude to 0.025. (b) Theoretical calculation of the power spectrum based on the solution of Eq. (4). In both plots synchronization occurs when $|i_b| < 1$ and sidebands are observed when $|i_b| > 1$.

FIG. 3: Measured power spectrum (in dB units) vs. detuning for the case where $\omega_d/\Omega_{\text{eff}} \simeq 1/2$. Other experimental parameters are listed in the caption of Fig. 2.

VII. RESONANCE DETECTION IN THE REGION OF SYNCHRONIZATION

The effect of noise, which is assumed to be weak, can be taken into account by linearizing Eq. (4), which becomes

$$\frac{d\gamma_n}{d\tau} + \gamma_n \cos \gamma = i_n,$$  \hspace{1cm} (5)

where $\gamma$ represents a solution in the noiseless case and $\gamma_n$ is a fluctuating term added to $\gamma$ due to noise. For the case $|i_b| < 1$ one finds from the stationary solution of Eq. (4) that $\cos \gamma = \sqrt{1 - i_b^2}$. The power spectrum $S_\gamma (w)$ of $\gamma_n$ as a function of the dimensionless angular frequency $w$ can be found using Eq. (6) and the autocorrelation function $\langle i_n(\tau) i_n(\tau') \rangle$

$$S_\gamma (w) = \frac{\Theta}{\pi \omega_b r_0^2} \frac{1}{1 - i_b^2 + w^2}.$$  \hspace{1cm} (6)

The correlation function $C_\gamma (\tau') = \langle \gamma_n (\tau + \tau') \gamma_n (\tau) \rangle$ can be determined using the Wiener-Khinchine theorem

$$C_\gamma (\tau') = \int_{-\infty}^{\infty} dw \ e^{iw\tau'} S_\gamma (w) = \frac{\Theta e^{-\sqrt{1 - i_b^2} |\tau'|}}{\omega_b r_0^2 \sqrt{1 - i_b^2}},$$  \hspace{1cm} (7)

and thus the following holds

$$\langle \exp (i (\gamma_n (\tau + \tau') - \gamma_n (\tau))) \rangle = 1 - \gamma_k |\tau'| + O (|\tau'|^2),$$

where $\gamma_k$, which is given by $\gamma_k = \Theta / \omega_b r_0^2$, is the jitter rate. Note that $\gamma_k$ is independent on $i_b$. In terms of the the energy $U_0$ stored in the mechanical resonator the dimensionfull jitter rate is given by $\omega_b \gamma_k = (k_B T_{\text{eff}} / U_0) \gamma_0$. Note that the same jitter rate is obtained for the case of FO (provided that $U_0$ is unchanged).
In the region of synchronization, i.e. when $|b_0| < 1$, the resonance frequency $\Omega_{\text{eff}}$ can be determined by monitoring the relative phase $\gamma$. Consider an estimate of the averaged value of $\gamma$ based on a sampling of the signal $\gamma + \gamma_0 (\tau)$ over a sampling time of duration $\tau_\alpha$. The standard deviation $\delta_\gamma$ in this estimate is given by

$$\delta_\gamma = \left( \frac{2\pi S_\gamma (0)}{\tau_\alpha} \right)^{1/2} = \left( \frac{2\Theta}{\omega_a \tau_\alpha \gamma_0^2 (1 - t_0^2)} \right)^{1/2} . \quad (8)$$

The corresponding deviation $\delta_\Omega$ in the estimated value of $\Omega_{\text{eff}}$ is given by $\delta_\Omega = R \delta_\gamma$, where the responsivity $R$ is given by $R = (|d\gamma/d\Omega_{\text{eff}}|)^{-1} = \omega_a \sqrt{1 - t_0^2}$, and thus the normalized minimum detectable change in the frequency is given by $\delta_\Omega/\Omega_{\text{eff}} = \sigma_{\omega 0}$, where $\sigma_{\omega 0}$ is given by Eq. (1). Thus for the same given stored energy $U_0$ in the mechanical resonator the same sensitivity is expected in the regions of synchronization and FO. In other words, the above-discussed degradation in sensitivity occurring from Argonne National Laboratory, provided by the Director, Office of Science, of the U.S. Department of Energy under Contract No. DE-AC02-06CH11357.

**VIII. SUMMARY**

In summary, the sensitivity of a detector based on a mechanical resonator is studied in the SEO regime. It is found that phase noise can be suppressed by externally applying a modulation. Moreover, the transition from the regions of synchronization and free running SEO is explored, and a universal behavior referred to as the square-root law is revealed.

**IX. ACKNOWLEDGEMENTS**

On-fiber optomechanical cavities have been fabricated by former members of the Technion group K. Shlomi, D. Yuvuraj and I. Baskin. Argonne National Laboratory’s contribution is based upon work supported by Laboratory Directed Research and Development (LDRD) funding from Argonne National Laboratory, provided by the Director, Office of Science, of the U.S. Department of Energy under Contract No. DE-AC02-06CH11357.

**Appendix A: Evolution equation**

The theoretical model [33, 37] that is used to derive the evolution equation [33] is briefly described below. The micromechanical mirror in the optical cavity is treated as a mechanical resonator with a single degree of freedom $x$ having mass $m$ and linear damping rate $\gamma_0$ (when it is decoupled from the optical cavity). It is assumed that the angular resonance frequency of the mechanical resonator depends on the temperature $T$ of the suspended mirror. For small deviation of $T$ from the base temperature $T_0$ (i.e. the temperature of the supporting substrate) it is taken to be given by $\omega_0 - \beta T_R$, where $T_R = T - T_0$ and where $\beta$ is a constant. Furthermore, to model the effect of thermal deformation [28] it is assumed that a temperature dependent force given by $m \theta T_R$, where $\theta$ is a constant, acts on the mechanical resonator [33]. When noise is disregarded, the equation of motion governing the dynamics of the mechanical resonator is taken to be given by

$$\frac{d^2 x}{dt^2} + 2\gamma_0 \frac{dx}{dt} + \left(\omega_0 - \beta T_R\right)^2 x = \theta T_R . \quad (A1)$$

The intra-cavity optical power incident on the suspended mirror is denoted by $P_L x$, where $P_L$ is the injected laser power, and the function $I (x)$ depends on the mechanical displacement $x$ [see Eq. (A3) below]. The time evolution of the relative temperature $T_R$ is governed by the thermal balance equation

$$\frac{dT_R}{dt} = Q - \kappa T_R , \quad (A2)$$

where $Q = \eta P_L x$ is proportional to the heating power, $\eta$ is the heating coefficient due to optical absorption and $\kappa$ is the thermal decay rate.

The function $I (x)$ depends on the properties of the optical cavity that is formed between the suspended mechanical mirror and the on-fiber static reflector. The fineness of the optical cavity is limited by loss mechanisms that give rise to optical energy leaking out of the cavity. The main escape routes are through the on-fiber static reflector, through absorption by the metallic mirror, and through radiation. The corresponding transmission probabilities are respectively denoted by $T_B$, $T_A$ and $T_R$. In terms of these parameters, the function $I (x)$ is given by

$$I (x) = \frac{\beta_F \left(1 - \frac{\beta^2}{\beta_F^2}\right)}{1 - \cos \frac{4\pi x}{\lambda} + \beta^2} \frac{\beta^2}{\lambda} , \quad (A3)$$

where $x_D = x - x_R$ is the displacement of the mirror relative to a point $x_R$, at which the energy stored in the optical cavity in steady state obtains a local maximum, $\beta^2 = (T_R \pm T_A \pm T_B)^2/8$ and where $\beta_F$ is the cavity fineness. The reflection probability $R_C = P_R / P_L$ is given in steady state by $R_C = 1 - I (x) / \beta_F$. For sufficiently small $x$, the expansion $I (x) = I_0 + I'_0 x + (1/2) I''_0 x^2 + O (x^3)$ can be employed, where a prime denotes differentiation with respect to the displacement $x$.

Consider the case where the laser power $P_L$ is modulated in time according to $P_L (t) = P_0 + P_1 (t)$, where $P_0$ is a constant and $P_1 (t)$ is assumed to have a vanishing average. When both $P_1$ and $I - I_0$ are sufficiently small, the problem can be significantly simplified by employing the approximation $Q \simeq \eta P_0 I + \eta P_1 I_0$. The displacement $x (t)$ is expressed in terms of the complex amplitude $A$ as $x (t) = x_0 + 2 \text{Re} A$, where $x_0$, which is given
by \( x_0 = \eta \theta P_0 I_0 / k \omega_0^2 \), is the averaged optically-induced static displacement. For a small displacement, the evolution equation for the complex amplitude \( A \) is found to be given by Eq. (2) \([37, 42]\), where both the effective resonance frequency \( \Omega_{\text{eff}} \) and the effective damping rate \( \Gamma_{\text{eff}} \) are real even functions of \( |A| \). To second order in \( |A| \) they are given by \( \Gamma_{\text{eff}} = \Gamma_0 + \Gamma_2 |A|^2 + \Omega_{\text{eff}} = \Omega_0 + \Omega_2 |A|^2 \), where \( \Gamma_0 = \gamma_0 + \eta \theta P_0 I_0 / 2 \omega_0^3 \), \( \Omega_0 = \omega_0 - \beta P_0 I_0 / \kappa \), \( \gamma_2 = \eta \beta P_0 I_0 / 4 \omega_0 \), and \( \kappa \) is the intrinsic mechanical nonlinear quadratic damping rate \([66]\). \( \Omega_{\text{eff}} = \omega_0 - \beta P_0 I_0 / \kappa \) and \( \Omega_2 = -\beta P_0 I_0^2 / \kappa \). Note that the above expressions for \( \Gamma_{\text{eff}} \) and \( \Omega_{\text{eff}} \) are obtained by making the following assumptions: \( \kappa^2 / \omega_0^3 \lambda \ll \beta / \theta \ll 1 / 2 \omega_0 x_0 \) and \( \kappa \ll \omega_0 \), both typically hold experimentally \([36]\). The term \( \xi(t) \) in Eq. (2) represents the thermal force that is generated due to the laser power modulation. For the case of a monochromatic modulation at angular frequency \( \omega_d \) \( \ll \Omega_{\text{eff}} \) it is given by \( \xi(t) = \eta P_0 I_0 \Omega_0^2 e^{-i \omega_d t} \).

**Appendix B: Monochromatic modulation with \( \omega_d \ll \Omega_{\text{eff}} \)**

In cylindrical coordinates the complex amplitude of mechanical oscillation \( A \) is expressed as \( A = A_r e^{i \xi} \), where \( A_r = \sqrt{A_x^2 + A_y^2} \) is positive, \( A_r \) is real \([67]\), and Eq. (2) is written as

\[
\dot{A}_r + A_r \Gamma_{\text{eff}} = \xi_r + \vartheta_r , \tag{B1}
\]

and

\[
\dot{A}_\theta + \Omega_{\text{eff}} (A_r) = \frac{\xi_\theta + \vartheta_\theta}{A_r} , \tag{B2}
\]

where

\[
\xi_r = \frac{A_x \xi_x + A_y \xi_y}{A_r} , \tag{B3}
\]

\[
\vartheta_r = \frac{A_x \vartheta_x + A_y \vartheta_y}{A_r} , \tag{B4}
\]

\[
\xi_\theta = \frac{A_x \xi_y - A_y \xi_x}{A_r} , \tag{B5}
\]

\[
\vartheta_\theta = \frac{A_x \vartheta_y - A_y \vartheta_x}{A_r} , \tag{B6}
\]

\( A = A_x + i A_y \), \( \xi = \xi_x + i \xi_y \), where \( A_x, A_y, \xi_x \) and \( \xi_y \) are all real, and the noise terms satisfy the following relations

\[
\langle \vartheta_r (t) \vartheta_r (t') \rangle = 2 \Theta \delta (t - t') , \tag{B7}
\]

\[
\langle \vartheta_\theta (t) \vartheta_\theta (t') \rangle = 2 \Theta \delta (t - t') , \tag{B8}
\]

\[
\langle \vartheta_r (t) \vartheta_\theta (t') \rangle = 0 . \tag{B9}
\]

Consider the case of a monochromatic modulation at angular frequency \( \omega_d \), which is assumed to be close to the angular frequency \( \Omega_{\text{eff}} \). When fluctuations in the amplitude \( A_r \) of SEO are disregarded, i.e. when it is assumed that \( A_r = r_0 \), Eq. (B1) becomes [see Eq. (B5)]

\[
\dot{A}_\theta + \Omega_{\text{eff}} = -\omega_d \sin (A_\theta + \omega_d t) + \frac{\vartheta_\theta}{r_0} , \tag{B10}
\]

where \( \Omega_{\text{eff}} \) is treated as a constant and where \( \omega_d \), which is given by \( \omega_d = \eta \theta P_0 \Omega_0 / \Omega_0^2 r_0 \), represents the modulation amplitude. In terms of the relative phase \( \gamma = A_\theta + \omega_d t \) and the dimensionless time \( \tau = \omega_d t \) Eq. (B10) can be rewritten as

\[
\frac{d\gamma}{d\tau} + \sin \gamma = i_b + i_n , \tag{B11}
\]

where

\[
i_b = \frac{\omega_d - \Omega_{\text{eff}}}{\omega_a} , \tag{B12}
\]

and where \( i_n = \vartheta_\theta / (\omega_a r_0) \). With the help of Eq. (B8) one finds that

\[
\langle i_n (\tau) i_n (\tau') \rangle = \frac{2 \Theta}{\omega_a r_0^2} \delta (\tau - \tau') . \tag{B13}
\]

**1. The noiseless case**

Consider first the noiseless case, for which \( i_n = 0 \). Below the time evolution of \( \gamma \) in the region \( |i_b| > 1 \) is derived. Rewriting Eq. (B11) as \( d\tau = d\gamma / (i_b - \sin \gamma) \) leads by integration to

\[
\tau = \frac{2}{\sqrt{i_b^2 - 1}} \tan^{-1} \frac{i_b \tan \frac{\gamma}{2} - 1}{\sqrt{i_b^2 - 1}} . \tag{B14}
\]

Inverting this relation yields

\[
\gamma = 2 \tan^{-1} \left( 1 + \sqrt{i_b^2 - 1} \tan \frac{\pi \tau}{T_3} \right) , \tag{B15}
\]

where the normalized period time \( T_3 \) is given by

\[
T_3 = \frac{2 \pi}{\sqrt{i_b^2 - 1}} , \tag{B16}
\]

and thus

\[
A_\theta = 2 \tan^{-1} \left( \frac{1 + \sqrt{i_b^2 - 1} \tan \frac{\pi \omega_d t}{i_b}}{i_b} \right) - \omega_d t . \tag{B17}
\]

The averaged derivative \( \langle d\gamma / d\tau \rangle \) is related to the period time \( T_3 \) by

\[
\langle \frac{d\gamma}{d\tau} \rangle = \frac{1}{T_3} \int_0^{T_3} \frac{d\gamma}{d\tau} d\gamma = \frac{2 \pi}{T_3} , \tag{B18}
\]

thus [see Eqs. (B12) and (B10)]

\[
\langle \frac{d\gamma}{d\tau} \rangle = \sqrt{i_b^2 - 1} , \tag{B19}
\]
and

\[ -\left\langle \frac{dA_d}{dt} \right\rangle = \begin{cases} \omega_d \theta \frac{\omega_d}{\omega_a} - \frac{\omega_d}{\omega_a} \sqrt{i_b^2 - 1} & \text{if } |i_b| < 1 \\ \omega_d - \omega_a \sqrt{i_b^2 - 1} & \text{if } |i_b| \geq 1 \end{cases} \]  \tag{B20} \]

Therefore, the signal \( \cos A_d \) when \(|i_b| \geq 1\) has Fourier spectrum made of peaks at the angular frequencies \( \omega_d + n\omega_s \), where \( n \) is an integer and the sideband spacing \( \omega_s \), which is given by \( \omega_s = 2\pi\omega_s/T_J = \sqrt{(\omega_d - \Omega_{\text{eff}})^2 - \omega_d^2} \) [see Eqs. (B12) and (B16)], depends on both the amplitude \( \omega_s \) and frequency \( \omega_d \) of the forcing term \( \xi = r_0\omega_a A_d e^{-i\omega_d t} \).

2. Fourier expansion

With the help of Eqs. (B11), (B15) and (B16) together with the identity \( \sin \theta = \sin \left( \frac{2\pi}{T_J} + x_0 \right) \), one finds that

\[ \frac{d\gamma}{dr} = \gamma \left( \frac{2\pi}{T_J} + x_0 \right) \]  \tag{B21} \]

where the function \( \gamma(x) \) is defined by

\[ \gamma(x) = \frac{i_b^2 - 1}{i_b + \sin x} \]  \tag{B22} \]

and where

\[ x_0 = \tan^{-1} \frac{1}{\sqrt{i_b^2 - 1}} \]  \tag{B23} \]

The Fourier expansion of the function \( \gamma(x) \) is expressed as [see Eq. (B22)]

\[ \gamma(x) = \sum_{k=-\infty}^{\infty} g_k e^{ikx} \]  \tag{B24} \]

where

\[ g_k = \frac{i_b}{|i_b|} \sqrt{i_b^2 - 1} e^{-1} \left( \frac{i_b}{i_b} \sqrt{i_b^2 - 1} \right)^{|k|} \]  \tag{B25} \]

Thus, the magnitude of the sideband peaks is relatively large when \(|i_b| \geq 1\). For \(|i_b| \gg 1\) the sidebands become small, and the relative phase becomes \( \gamma \simeq (\omega_d - \Omega_{\text{eff}}) t \) [see Eq. (B15)], i.e. the effect of laser modulation becomes weak.

Appendix C: Square root law

In each of the regions of phase locking [48, 49] the so-called winding number, which measures the oscillator phase accumulation relative to the phase of the drive, shows a plateau [50, 68, 70]. For concreteness, consider the region just outside the primary plateau where (for positive \( i_b \)) \( 0 < i_b - 1 \ll 1 \), where \( i_b \) is the normalized detuning (recall that \(|i_b| = 1\) at the onset of synchronization). The dimensionless frequency \( T_J^{-1} \) in this region is related to the critical parameter \( i_b \) by \( T_J^{-1} \simeq 2^{-1/2} \pi^{-1} \sqrt{i_b - 1} \) [see Eq. (B10)]. Below it is shown that a similar “square root law” can be obtained for the region just outside any other plateau.

Consider a general 1D map having the form

\[ \theta_{n+1} = \theta_n - \alpha + W_a F(\theta_n) \]  \tag{C1} \]

that describes, e.g. the phase of the oscillator motion observed every period of the applied drive. The detuning \( \alpha \) is approximately \((\Omega_{\text{eff}} - \omega_a)2\pi/\omega_d \). \( W_a \) parametrizes the strength of applied periodic drive (zero in the absence of drive). The “map function” is a periodic real function, if we assume that the phase at the sampling step \( n + 1 \) only depends on phase at step \( n \), and the phases \( \theta \) and \( \theta + 2\pi \) are physically indistinguishable, \( F(\theta + 2\pi) = F(\theta) \).

If the drive frequency is near the oscillator frequency, then the detuning is close to zero. The phase locking corresponds to a stable fixed point of the map, which can be found by solving the equation \( \theta_{n+1} = \theta_n \equiv \theta^* \), that is

\[ \alpha = W_a F(\theta^*) \]  \tag{C2} \]

where \( \theta^* \) is the stroboscopic value of the oscillator phase at the fixed point. Since the function \( F \) is continuous and periodic, it is bounded, and the fixed point of this map only exists for a small enough detuning.
Suppose now that the drive frequency is an integer fraction of the oscillator frequency, \( \omega_d \approx \Omega_{\text{eff}}/p \). Then, since the phase is defined modulo \( 2\pi \), the effective detuning in this case is still small and the analysis of the locking transition is based on the same map equation. The locking will occur to \( \Omega_{\text{eff}} = p\omega_d \). On the other hand, if the frequency of the drive is an integer multiple \( \omega_d \approx p\Omega_{\text{eff}} \) of the oscillator frequency, then during one period of the drive, oscillator will only accrue a fraction \( \approx 2\pi/p \) phase, which in general will correspond to too large of a detuning over single period of the drive to allow for a fixed point solution. However, the problem can be reduced to a formally equivalent one by iterating the map \( p \) times,

\[
\theta_{n+p} = \theta_n - p\alpha + \tilde{W}_n \tilde{\mathcal{F}}(\theta_n),
\]

where the effective detuning \( p\alpha \) is now close to \( 2\pi \), and the original treatment for the simple locking applies, with the resulting locked frequency being \( \Omega_{\text{eff}} = \omega_d/p \). Note however, that the amplitude and the form of the map function are now different, and generically smaller in magnitude that the \( p = 1 \) case. This makes locking to high frequency drives in general less stable.

Now, let us look more carefully at the transition out of the locking regime as a function of detuning, \( \alpha \). Let us define \( \alpha_c \) as the value of detuning and \( \theta_c \) as the value of the fixed point \( \theta^* \) at the transition between locked and the running phase (unlocked) regimes, \( \theta_c = \theta^*(\alpha_c) \). At the critical detuning, the slope of the map function \( \mathcal{F} \) vanishes (see Figure 4). We can expand the map function around this point up to the second order,

\[
\mathcal{F}(\theta) = \frac{\alpha_c}{W_n} \left[ 1 - z^2 (\theta - \theta_c)^2 \right] + O \left( (\theta - \theta_c)^3 \right),
\]

where \( z \) is a parameter that characterizes the curvature of the map function near \( \theta_c \). Indeed, as can be seen from Eq. [C1], the map has a fixed point (i.e. a solution to the equation \( \theta_{n+1} = \theta_n \)) provided that \( \alpha < \alpha_c \) (the fixed point is given by \( \theta^* = \theta_c + \sqrt{1 - \alpha/\alpha_c} \)).

On the unlocked side, it is convenient to treat the discreet series \( y_n = \theta_n - \theta_c \) as a continuous function \( y(n) \), since near \( \theta_c \) each iteration step changes \( \theta \) only slightly ("staircase" diagram in Figure 4). Then, from [C1] and [C4]

\[
\frac{dy}{dn} = \alpha_c - \alpha - \alpha_c z^2 y^2.
\]

This equation can be easily integrated in order to determine how long it takes the phase to pass through the bottleneck (Fig. 4). For that, the limits of integration over \( y \) can be extended to the full real axis (details of the map function away from \( \theta_c \) do not matter in this regime, since it takes much shorter time to go through regions other than the bottleneck).

Thus the estimate for the total number of drive periods for the phase to wind by \( 2\pi \) relative to the drive, is

\[
N(\alpha) = \frac{1}{\alpha - \alpha_c} \int_{-\infty}^{\infty} \frac{dy}{1 + \frac{\alpha - \alpha_c}{\alpha - \alpha_c} z^2 y^2} = \frac{\pi}{z \sqrt{\alpha - \alpha_c}}.
\]

This translates into the time period \( T_{\text{LC}} = 2\pi N(\alpha)/\omega_d \) per \( 2\pi \) phase slip. Thus, the periodic oscillation of \( y \) gives rise to sideband spectral peaks split from the drive frequency by integer multiples of \( 2\pi/T_{\text{LC}} \propto \sqrt{\alpha - \alpha_c} \).
