Resistance to ABT-737 in activated T lymphocytes: molecular mechanisms and reversibility by inhibition of the calcineurin–NFAT pathway

PE Cippi1,2, AK Kraus1,2, MT Lindenmeyer1,2, J Chen1,2, A Guimezanes3, PD Bardwell4, T Wekerle5, RP Wüthrich1,2 and TFehr1,2

Dynamic regulation of the intrinsic apoptosis pathway controls central and peripheral lymphocyte deletion, and may interfere with the pro-apoptotic potency of B-cell lymphoma 2 inhibitors such as ABT-737. By following a T-cell receptor (TCR) transgenic population of alloantigen-specific T cells, we found that sensitivity to ABT-737 radically changed during the course of allo-specific immune responses. Particularly, activated T cells were fully resistant to ABT-737 during the first days after antigen recognition. This phenomenon was caused by a TCR–calcineurin–nuclear factor of activated T cells-dependent upregulation of A1, and was therefore prevented by cyclosporine A (CsA). As a result, exposure to ABT-737 after alloantigen recognition induced selection of alloreactive T cells in vivo, whereas in combination with low-dose CsA, ABT-737 efficiently depleted alloreactive T cells in murine host-versus-graft and graft-versus-host models. Thus, ABT-737 resistance is not a prerogative of neoplastic cells, but it physiologically occurs in T cells after antigen recognition. Reversibility of this process by calcineurin inhibitors opens new pharmacological opportunities to modulate this process in the context of cancer, autoimmunity and transplantation. Cell Death and Disease (2012) 3, e299; doi:10.1038/cddis.2012.38; published online 19 April 2012

Subject Category: Experimental Medicine

B-cell lymphoma 2 (Bcl-2) inhibition represents a novel pharmacological principle to control lymphoid malignancies and detrimental immune responses. Of particular scientific and potential clinical interest are the small molecule Bcl-2 inhibitors ABT-737 and its bioavailable counterpart Navitoclax (ABT-263). ABT-737 binds with high affinity to the anti-apoptotic Bcl-2 family members Bcl-2, Bcl-XL and Bcl-w. By this mechanism, it prevents them from sequestering pro-apoptotic BH3 proteins, and therefore, indirectly initiates the apoptotic cascade. In contrast, ABT-737 has a low affinity to Bcl-2-A1 (A1, Bfl-1), Mcl-1 and Bcl-B. These particular molecular binding characteristics may be important for tissue selectivity and – as a consequence – for the favorable toxicity profile of ABT-737 and ABT-263, but limits their therapeutic potency on lymphoma cells expressing A1 and Mcl-1.

The physiological regulation of apoptosis in lymphocytes has been extensively investigated, and may assume a new relevance in the context of therapeutic approaches selectively targeting Bcl-2 proteins. Focusing on the T-cell compartment, it has been shown that the fate of a T cell is linked to the expression of a functional T-cell receptor (TCR) and its interaction with antigen-presenting cells (APCs). The combination of signals through the TCR, co-stimulatory molecules (such as CD28 and 4-1BB) and cytokines (such as interleukin (IL)-2 and IL-15) dynamically modulates the intrinsic and the extrinsic apoptosis pathway in T lymphocytes, and eventually controls central and peripheral T-cell selection. Of particular interest are previous reports on a TCR-dependent upregulation of A1 in the early phase after antigen recognition, which protects activated thymocytes and splenocytes from apoptosis without interfering with cell proliferation. These mechanisms are crucial for the development and maintenance of a functional immune system and might be influenced by drugs targeting the apoptosis pathway.

This hypothesis is supported by previous reports about the immuno-modulatory properties of ABT-737 in several experimental models: ABT-737 had a beneficial effect on autoimmunity and significantly inhibited solid allograft rejection in mice. However, immunosuppression by ABT-737 in a collagen-induced arthritis model was only effective in a preventive setting, but not in mice with established disease. Furthermore, the immunosuppressive effect of ABT-737 in a murine skin graft model was rather limited as a single agent, but markedly increased in combination with cyclosporine A (CsA). These data suggest that the pro-apoptotic potency of ABT-737 on lymphoid cells is altered in the context of inflammation and T-cell activation.
In this study, we examined the effect of ABT-737 on alloreactive T cells in the setting of host-versus-graft (HvG) and graft-versus-host (GvH) immune reactions. We found a unique selectivity profile of ABT-737 on T lymphocytes over the course of the immune response as a result of a transient, calcineurin-, nuclear factor of activated T cells (NFAT)- and A1-dependent resistance to ABT-737 after antigen recognition. The calcineurin inhibitor CsA blocked A1 upregulation and prevented resistance to ABT-737 in activated T cells, thereby offering new options for effective combination therapies.

Results

Activated T cells are resistant to ABT-737. To investigate the impact of allogeneic T-cell activation on the sensitivity to the Bcl-2 inhibitor ABT-737, we used the transgenic mouse strain BM3.3, which expresses on all CD8 T cells a transgenic TCR specific for the major histocompatibility complex (MHC) class I molecule H-2K^b and can be detected by the clonotypic antibody Ti98. In the first experiment, we transplanted BM3.3 bone marrow into non-lethally irradiated CBA mice to create synchimeric mice that express the BM3.3 TCR only on a fraction of the CD8 T-cell pool. This well-defined homogeneous population of alloreactive CD8 T cells could then be followed during the course of an HvG response in the context of an otherwise physiological immune system (Figures 1a and b). Synchimeras received a donor-specific transfusion (DST) (20 × 10^6 B6 splenocytes, i.v., DST) and treatment with either ABT-737 (50 mg/kg per day) or vehicle, starting at day 2 after DST. At day 5 after priming, mice treated with ABT-737 presented a 75% reduction of T cells in peripheral blood (Figure 1c); CD4 and CD8 T cells were similarly affected by the treatment (Figure 1d). After antigen recognition, the percentage of Ti98^+ cells among CD8 T cells increased in both groups, but this effect was markedly enhanced in the ABT-737 group compared with control (Figure 1e). This observation is explained by a selection of activated Ti98^+ cells among CD8 T cells under the effect of ABT-737, which

Figure 1 Alloreactive CD8 T cells are resistant to ABT-737 after DST. (a) Characterization of the BM3.3 model; after 48 h of MLR with BM3.3 responders and CD8-depleted B6 stimulators, all responder (Ti98^+) CD8 T cells were activated, as measured by CD25 expression in FACS. (b) Experimental setup: synchimeric mice were generated by bone marrow (BM) transplantation from BM3.3 mice into CBA recipients after non-lethal total body irradiation (3 Gy). After 6 weeks, synchimeras expressed the BM3.3 TCR (Ti98^+) on about 6% of the whole CD8-positive population. The mice were primed by i.v. injection of B6 splenocytes, and 2 days later, treatment with ABT-737 was started. (c and d) Exposure to ABT-737 induced a relative and absolute reduction of CD3^+ cells in peripheral blood, and similarly affected CD4^+ and CD8^+ T cells. (e) The increase of the percentage of Ti98^+ cells among CD8 T cells was significantly higher in mice exposed to ABT-737 (P < 0.01). Statistical comparison of data registered at baseline and at day 5 by paired t-test; *P < 0.05, **P < 0.01; n = 5. Representative results of one of two independent experiments are shown.
Resistance to ABT-737 in activated T lymphocytes

PE Cippik et al

may be further enhanced by homeostatic proliferation in a lymphopenic environment.

To limit the confounding effect of homeostatic proliferation, we performed an analogous experiment in a GvH model. The combination of a parent to F1 model with the BM3.3 transgenic system allowed us to specifically analyze a homogeneous population of host-reactive CD8 T cells in the absence of rejection by the recipient and without the effect of any conditioning regime (such as total body irradiation) that may alter the immune response and apoptosis regulation. We minimized the effect of T-cell proliferation by choosing a short protocol: BM3.3 splenocytes were adoptively transferred into (CBAxB6)F1 (allogeneic stimulation) or CBA recipients (syngeneic control). On day 1 after transfer treatment with ABT-737 (50 mg/kg per day) or vehicle was started, and 2 days later, recipient mice were killed for fluorescence-activated cell sorting (FACS) analysis. ABT-737 minimally influenced the activation of Ti98+ cells (Figures 2c and d) and similarly reduced the number of total splenocytes in F1 and CBA recipients by about 30% reduction (Figures 2e and f). However, in the syngeneic combination, Ti98+ cells were equally reduced as total T cells and total splenocytes (Figures 2e and g), whereas in F1 recipients, alloactivated donor-reactive CD8+Ti98+ cells were resistant to ABT-737 (Figure 2h). As a result, the total number of Ti98+ cells in CBA recipients was markedly reduced after ABT-737 treatment, but no difference in the total number of Ti98+ cells between the two groups was registered after allogeneic stimulation (Figures 2g and h). These data strongly suggest that resistance of activated Ti98+ T cells to ABT-737 had developed in both HvG and GvH experiments.

This hypothesis was further tested in vitro in a mixed lymphocyte reaction (MLR) model. BM3.3 splenocytes were cultured with CD8-depleted allogeneic B6 or syngeneic CBA splenocytes during 48 h and then treated with ABT-737 for an additional 12 h. Cell viability analysis by propidium iodide (PI) exclusion in FACs revealed that a 1000- to 10,000-fold higher concentration of ABT-737 was required to induce apoptosis in CD8 T cells after allogeneic stimulation (Figure 3a). To exclude a transgenic artifact, the same experiment was repeated with B6 responders and T-cell-depleted CBA stimulators. Activated (CD25+) CD8 T cells were much more resistant to ABT-737 compared with non-activated (CD25−) cells in the same culture and to syngeneically stimulated (non-activated) T cells. The same phenomenon was observed for CD4 T cells (Figure 3b). Thus, T-cell activation induces resistance to ABT-737 in vitro and in vivo.

Molecular mechanism of resistance to ABT-737 in activated T cells. The regulation of apoptosis is complex, and several mechanisms may be involved in resistance to ABT-737 after T-cell activation. In MLR experiments using the BM3.3 system, we found that exposure to the ribosome blocker cycloheximide during the stimulation phase prevented the establishment of ABT-737 resistance, indicating that protein synthesis was required to induce this anti-apoptotic state (Figure 4a). Previous studies in tumor models revealed that the expression of anti-apoptotic Bcl-2 proteins with a low binding affinity to ABT-737, such as A1 and Mcl-1, resulted in resistance to this compound.21 Therefore, we first assessed the impact of T-cell activation on the expression of various anti-apoptotic Bcl-2 factors in our system. Analyses by quantitative RT-PCR (qRT-PCR) revealed that T-cell activation rapidly influenced the gene expression pattern of Bcl-2 family members (Figure 4b); among the Bcl-2 members that are not inhibited by ABT-737, expression of A1 was nine-fold higher in alloantigen-stimulated than in non-activated cells. In contrast, expression of Mcl-1 did not change. When looking at time kinetics, we found that resistance to ABT-737 is a transient phenomenon; it rapidly develops after T-cell activation.
stimulation, but progressively vanished after 4–5 days of culture (Figure 4c). This evolution strongly correlated with expression of A1 protein over time (Figure 4d), supporting the hypothesis of a crucial role of this particular factor. A selective inhibition of A1 in murine cells is complicated because of the presence of four homologous genes for A1 in the mouse genome. Just one of them – A1-α – was successfully targeted in a knock-out mouse, and selective pharmacological A1 inhibitors are currently not available. Therefore, we applied a reversed approach using different Bcl-2 inhibitors with a defined binding profile. We found that T-cell activation induced resistance to Bcl-2 inhibition by ABT-737 (no binding of A1 and Mcl-1) and by Antimycin A (no binding of A1 only), but had no impact on the pro-apoptotic potency of the pan-Bcl-2 inhibitor obatoclax (Figure 4e). Thus, A1 upregulation is the crucial factor determining resistance to ABT-737 in activated T cells.

T-cell activation and resistance to ABT-737. According to the three-signal concept, physiological T-cell activation is determined by the concurrent stimulation of the TCR (signal 1), together with a costimulatory signal through CD28 and CD154 (signal 2), and by the effect of cytokines such as IL-2 and IL-15 (signal 3). The link between resistance to ABT-737 and the different pathways involved in T-cell activation was investigated dissecting the T-cell activation process by blockade of different pathways during the stimulation phase (24 h). We found that resistance to ABT-737 was prevented by blocking signal 1 with the calcineurin inhibitor CsA. In contrast, blocking of CD28 signaling by CTLA4 Ig or of CD40 signaling by MR1 or using CD40 knock-out stimulators (data not shown), and blocking of mTOR signaling by rapamycin at a concentration that efficiently inhibited MLR in the same combination, did not influence resistance to ABT-737 (Figure 5a). An important role of the TCR–calcineurin–NFAT (signal 1) cascade was further confirmed by using the alternative calcineurin inhibitor tacrolimus and the cell permeable NFAT-inhibitor VIVIT-R. The blockade of this pathway at any level increased the percentage of apoptotic cells in allogeneic, but not in syngeneic cultures (data not shown), and it prevented resistance to ABT-737 (Figure 5b), thereby excluding an off-target effect of CsA and indicating a crucial role for NFAT in preventing T-cell apoptosis in the early phase after antigen recognition. The correlation of these findings with the inhibition of upregulation of A1 by CsA was confirmed at the mRNA and protein level (Figures 5c and d). Thus, antigen recognition induced an NFAT-dependent upregulation of A1 that determined resistance to ABT-737 in alloantigen-activated CD8 T cells, and CsA completely prevented this resistance to ABT-737 in activated cells in vitro.

Reversibility of ABT-737 resistance by CsA in vivo. The critical role of signal 1 for ABT-737 resistance offers the opportunity to prevent resistance to ABT-737, using clinically well-established calcineurin inhibitors. We tested this option using a combination of CsA and ABT-737 in the GvH and HvG models introduced before. For the GvH experiments, BM3.3 splenocytes were transferred to F1 mice under treatment with low doses of CsA (10 mg/kg per day). Similar to the previous experiment (Figure 2), ABT-737 (50 mg/kg per day) was administered at day 1 and 2 after cell transfer, and on day 3, mice were killed for spleen FACS analysis. Concurrent with the in vitro results, the selection of activated donor-reactive CD8+ T cells observed in mice treated with ABT-737 alone was completely prevented by the addition of CsA (Figure 6a). Because of the general lymphopenia induced by ABT-737, this resulted in a much more pronounced depletion of alloreactive T cells in the combination group (Figure 6b). This effect was even more pronounced in the HvG model, where treatment was continued for 5 days after DST, and the immunosuppressive effect of CsA simultaneously contributed to the inhibition of the allogeneic immune response (Figure 6c). Thus, resistance to ABT-737 after antigen recognition was successfully overcome by combination with low doses of CsA.

Discussion

The regulation of the intrinsic apoptosis pathway in lymphocytes assumes a novel relevance after the advent of
small-molecule Bcl-2 inhibitors. Here we present evidence that sensitivity to ABT-737 in T lymphocytes dynamically changes during the course of an immune response; that is, activated T cells are transiently resistant to ABT-737 during the first days after antigen recognition, because of a signal-1-dependent, NFAT-dependent upregulation of A1. As a result, ABT-737 displayed a unique selectivity profile in its pro-apoptotic potency, depleting naive lymphocytes, but sparing T cells after antigen-specific activation.

A1 is upregulated in the first hours after T-cell activation and protects activated thymocytes and splenocytes from premature death.\textsuperscript{16,17} A1-dependent resistance to ABT-737 has been previously reported in lymphoma cells.\textsuperscript{6,7,26} Here we show for the first time that physiological upregulation of A1
after antigen recognition and ABT-737 resistance in normal (non-neoplastic) T cells are linked. More precisely, T-cell activation resulted in a 1000- to 10 000-fold resistance to ABT-737, a finding reminiscent of the results obtained by Vogler et al. in B-cell lymphoma cells cultured with CD154-expressing fibroblasts and IL-2. Mechanistic analyses revealed that the TCR–calcineurin pathway controlled the A1 upregulation, and that NFAT was the crucial transcription factor in this context, thereby mimicking the mechanism regulating A1 in mast cells after IgE receptor stimulation. Interestingly, fundamentally different pathways were involved in resistance to ABT-737 in CLL cells (which was signal 2- and 3-dependent and NFκB-mediated), suggesting a different regulation of A1 in B and T lymphocytes. In the complex system of apoptosis regulation, it is possible that additional factors may influence the sensitivity of T cells to Bcl-2 inhibition during the course of the immune response (e.g., Mcl-1 protein stabilization). However, we demonstrated that blocking A1 was critical to prevent resistance to ABT-737, and inhibiting signal 1 of T-cell activation achieves this goal.

The synergistic effect of CsA and ABT-737 is partially paradoxical because of the anti-apoptotic properties of CsA, which have been previously related to a stabilization of the mitochondrial membrane. This effect is presumably of limited relevance in combination with ABT-737. In contrast, the inhibition of the A1-dependent strong anti-apoptotic signal provided by the Ca²⁺–calcineurin–NFAT pathway was crucial to prevent resistance to ABT-737 in activated T cells, as shown by the similar effect obtained with tacrolimus and VIVIT-R. Interestingly, a dysregulation of the Ca²⁺–calcineurin–NFAT pathway has been described in several lymphatic and solid tumors, and may therefore influence the anti-neoplastic effect of Bcl-2 inhibitors. The most important consequence of the signal 1 dependency of ABT-737 resistance described here is the possibility to easily prevent it by well-established drugs such as calcineurin inhibitors. Characterization of ABT-737 resistance in physiological processes is relevant to find pharmacological strategies to potentiate the effect of Bcl-2 inhibitors, and although the use of immunosuppressive drugs to control cancer may be

**Figure 5**  Signal 1 determines resistance to ABT-737 in activated T cells. (a) Selective inhibitors of signal 1, 2 and 3 were added to an MLR during the stimulation phase with BM3.3 splenocytes reacting against CD8 T-cell-depleted B6 splenocytes to investigate the role of the different T-cell activation pathways for resistance to ABT-737 (1 μM, during additional 12 h of culture). The calcineurin inhibitor and signal 1 blocker CsA prevented resistance to ABT-737 in a concentration-dependent manner, whereas inhibition of signal 2 by CTLA4Ig and signal 3 by rapamycin did not influence this process. (b) The results obtained with CsA were confirmed by other inhibitors of the same pathway, namely the alternative calcineurin inhibitor tacrolimus and the NFAT inhibitor VIVIT-R. Cell viability of BM3.3 CD8 T cells was assessed by PI exclusion in FACS in at least three independent experiments. Percentage of cells treated with vehicle is given. Statistical comparison of ABT-737 versus vehicle: *P < 0.05, **P < 0.01. (c and d) Exposure to CsA during the stimulation phase inhibited the upregulation of A1 as assessed by qRT-PCR (c) and western blot (d)

**Figure 6**  CsA prevents resistance to ABT-737 in vivo. (CBA × B6)F1 mice were injected with BM3.3 splenocytes to induce a GvH reaction, and treated with ABT-737 (50 mg/kg per day, i.p.) with or without CsA (10 mg/kg per day, s.c.). After 3 days, the mice were killed and the spleens were analyzed by FACS. (a) Treatment with ABT-737 alone resulted in the selection of alloreactive Ti98+ cells. However, this phenomenon was completely prevented in combination with CsA (statistical comparison with vehicle or CsA alone, respectively). (b) As a result, the total number of alloreactive CD8+ Ti98+ cells per spleen was markedly reduced in the combination therapy group, compared with CsA or ABT-737 alone. (c) Similarly, in an HvG combination using synchimeric mice (Figure 1 for experimental setup), the combination of ABT-737 and CsA strongly reduced the number of donor-reactive Ti98+ cells as measured in spleens at day 5 after injection of B6 splenocytes. Statistical comparison to vehicle group: n.s. P > 0.05, 10.000 P 20.000 40.000 60.000 80.000 100.000 0 100 200 300 400 500 600 700 800 900 1000 Ti98+ among CD8+ GvH

Resolution to ABT-737 in activated T lymphocytes

PE Cippà et al
counterintuitive and potentially dangerous, we speculate that the combination of calcineurin inhibitors with ABT-737 might be beneficial in selected cases.

Because of the different molecular affinities of small-molecule Bcl-2 inhibitors to different members of the Bcl-2 family,1 their immuno-modulatory effect strictly depends on the expression of different members of the Bcl-2 family in distinct lymphocyte subpopulations and during the different phases of an immune response. Myeloid cells express high levels of Mcl-1 and are not affected by ABT-737; in contrast, ABT-737 efficiently induces apoptosis in naive lymphocytes.19,20 Here we demonstrate that the physiological mechanisms that protect T cells from apoptosis in the initial phase after antigen recognition dramatically influence their sensitivity to ABT-737. Particularly, the low affinity of ABT-737 to A1 determines a selection of antigen-specific T cells in the first days after activation. This explains why ABT-737 as an immunosuppressive agent is not effective during the first days after transplantation and in the acute phase of an autoimmune disease,21 but may find a clinical application for induction therapy before solid organ or stem cell transplantation. In contrast, we speculate that an opposite result would be obtained with a selective A1 inhibitor, but none of the currently available Bcl-2 inhibitors selectively binds to A1. However, the fact that ABT-737, in combination with CsA, efficiently depleted activated T cells in a GvH and an HvG model explains the synergistic effect of ABT-737 and CsA, which we previously observed in a skin graft model.19 and is a reasonable option to potentiate the immunosuppressive effect of Bcl-2 inhibitors.

Finally, the unique selectivity profile of ABT-737 may find a useful application for cell-based immunotherapy. The experimental selection of antigen-specific cells after a short activation time is difficult to achieve and largely limited to the use of transgenic systems. ABT-737 allows selecting polyclonal antigen-specific T cells in the first days after activation. This explains why ABT-737 as an immunosuppressive agent is not effective during the first days after transplantation and in the acute phase of an autoimmune disease, but may find a clinical application for induction therapy before solid organ or stem cell transplantation. In contrast, we speculate that an opposite result would be obtained with a selective A1 inhibitor, but none of the currently available Bcl-2 inhibitors selectively binds to A1. However, the fact that ABT-737, in combination with CsA, efficiently depleted activated T cells in a GvH and an HvG model explains the synergistic effect of ABT-737 and CsA, which we previously observed in a skin graft model. and is a reasonable option to potentiate the immunosuppressive effect of Bcl-2 inhibitors.

Materials and Methods

Mice, C57BL/6 (B6, H-2\(^b\)), CBA (H-2\(^d\), CBAxB6)F1 (F1, H-2\(^{ab+}\)) and BM3.3 (CBa background, H-2\(^d\)) mice were housed in specific pathogen-free conditions at the University of Zürich. The BM3.3 mouse, which expresses on all CD8 T cells a transgenic TCR selective for a naturally processed octapeptide bound to the allodigenic MHC class I molecule H-2K\(^d\), was kindly provided by A.-M. Schmitt-Verhulst. All animal experiments were performed according to protocols approved by the legal authority (Veterinary Office, Canton of Zürich, Switzerland).

Synchimeras and GvH reaction model. Synchimeric animals were generated as previously described. Briefly, 5 \times 10\(^5\) bone marrow cells from BM3.3 mice were transplanted into naive CBA mice irradiated with 3 Gy on the same day. After 6–10 weeks, B6 splenocytes were injected, and treatment with ABT-737 (50 mg/kg per day, intraperitoneally (i.p.)) or vehicle was started according to the experimental protocol. Donor-reactive BM3.3 CD8 T cells were monitored in blood using the Ti98 antibody, which selectively binds to the BM3.3 TCR.27

GvH reactions were studied in a parent to F1 model. The F1 mice were generated by breeding CBA females and B6 males, and expressed H-2\(^b\) and H-2\(^d\). After adoptive transfer of 20–25 \times 10\(^5\) BM3.3 splenocytes (H-2\(^d\) background and therefore not rejected by the host, and selectively reacting against H-2K\(^d\)), the GvH-reactive cells were analyzed in the spleen using the Ti98 antibody.

Fluorescence-activated cell sorting. FACS analyses were performed with a BD-FACSCanto II (Becton Dickinson, Basel, Switzerland); Anti-mouse CD3-FITC, CD4-PE, CD8-APC, and PI were purchased from eBioscience (Frankfurt, Germany); anti-mouse CD25-PE/Cy7 from Biolegend (Uithoorn, The Netherlands). The Ti98 antibody was kindly provided by A.-M. Schmitt-Verhulst. A secondary anti-mouse IgG was purchased from Becton Dickinson.

Mixed lymphocyte reaction. MLR were performed in 96-well plates with responder splenocytes stimulated by T-cell-depleted (or CD8 T-cell-depleted) splenocytes from allogeneic and syngeneic mice at a final concentration of 4 \times 10\(^5\) cells/ml. RPMI medium containing 10% fetal bovine serum, penicillin 100 U/ml, streptomycin 100 \mu g/ml, 2-mercaptoethanol 50 \mu M. Splenocytes were sorted by magnetic automatic cell separation using an autoMACS pro separator according to the protocols of MiltenyiBiotec (Bergisch Gladbach, Germany) to allow a selective analysis of responder CD4 and CD8 T cells in FACS.

Reagents and drugs. ABT-737 was provided by Abbott Bioresearch (Worcester, MA, USA); for in vitro experiments, ABT-737 was dissolved in dimethyl sulfoxide (DMSO) at a concentration of 5 mM, and then diluted in culture medium. For in vivo applications, ABT-737 was dissolved in polyethylene glycol, Tween 80, dextrose solution and DMSO, and injected i.p. at 50 mg/kg per day. Antimycin A, CsA, rapamycin and tacrolimus were purchased from EnzoBiochem (Farmingdale, NY, USA), cycloheximide from Sigma-Aldrich (Buchs, Switzerland), VIVIT-R from Calbiochem (Merck, Darmstadt, Germany), obatoclax (GX15-070) from Selleck (Houston, TX, USA). CTLA4Ig (abatacept) was provided by Bristol-Myers Squibb (Princeton, NJ, USA). The anti-CD154 (CD40L) antibody M1R was purchased from BioXCell (West Lebanon, NH, USA). For in vivo application, CsA was dissolved in ethanol and cromphylor EL (Sigma-Aldrich), then diluted in PBS and injected subcutaneously (i.c.).

Quantitative RT-PCR. Reverse transcription and qPCR were performed as reported earlier. Pre-developed TaqMan reagents were used for mouse Bcl-2 (Mm00477831_m1), Bcl-XL (Mm00437783_m1), Mcl-1 (Mm01257352_g1) and for the housekeeper gene 18S rRNA (Applied Biosystems Europe, Rotkreuz, Switzerland). For mouse A1, the following oligonucleotide primers and probe were designed to simultaneously detect Bcl-2A1a, Bcl-2A1b, and Bcl-2A1d. sense primer 5'-ATG GAG GTT GGG AAG ATG G-3', anti-sense primer 5'-GAG CCA AGG TTC TCT CTG GTC-3', fluorescence-labeled probe (FAM) 5'-GTC TGG CTG ACT TTT CTG CAG ATG-3'. The expression of candidate genes in alloantigen-stimulated cells of culture was normalized by 18S rRNA and compared with syngeneically stimulated cells.

Western blot. For western blot allo- and syngeneically stimulated lymphocytes were harvested with Rapi buffer and complete protease inhibitor cocktail (Roche, Mannheim, Germany) at different time points after stimulation in vitro. Extracted proteins were boiled in loading buffer for 5 min, resolved by 15% SDS-PAGE, and transferred to an Immobilon-P membrane (Millipore, Eschborn, Germany). Membranes were blocked overnight with Tris-buffered saline (TBS)/5% fat-free skim milk, then incubated with a polyclonal anti-A1 antibody (Cell Signaling Technology, Danvers, MA, USA) diluted 1 : 1000 overnight at 4 °C and rinsed with TBS that contained 0.1% Tween 20. For detection, an HRP-linked goat anti-rabbit antibody (1 : 4000, 30 min at room temperature; Cell Signaling Technology) and enhanced chemiluminescence substrate (Proteinsimple, Santa Clara, CA, USA) were used. Membranes were also probed with anti-actin antibody (A2066, 1 : 1000, Sigma-Aldrich) as internal loading control.
Conflict of Interest

FDB is an employee of Abbott, which developed and provided ABT-737. All other authors declare no conflict of interest.
