Introduction

The recent emergence and rapid increase of multi-drug resistant (MDR, resistance to more than three kinds of antibiotics) bacteria have caused public concern, represented by Escherichia coli resistant to carbapenem, colistin and tigecycline which were recognized as the last line of resort (Li et al., 2017; He et al., 2019; Ma et al., 2022). Due to incorrect use and misuse of antibiotics, the spread of antimicrobial resistance (AMR) is accelerating (Wang et al., 2022; Tang et al., 2022a,b). The continuous spread of AMR not only increases the difficulty of preventing and controlling livestock and poultry diseases but also seriously threatens livestock products' safety and endangers consumers’ health (Xu et al., 2022; Li et al., 2022a).

E. coli is a commonly used AMR indicator in human and food animal (Risola et al., 2019; Ma et al., 2022). There have been many reports on the study in E. coli and monitoring of the spread of AMR. The emergence of plasmid-mediated carbapenem resistance genes, especially blach3, has seriously affected the efficacy of meropenem (0.4%, 1/219; Tang et al., 2019, 2021b). Colistin resistance mediated by a plasmid-encoded mcr-1 was first documented in China during routine surveillance of food animals (21%, 166/804; Liu et al., 2016). A retrospective survey showed that mcr-1 was first traced back to 1980 but was not prevalent among bacteria until 2009 (Shen et al., 2016). With the detection rate of mcr-1 in bacteria increasing year by year, a relatively high occurrence rate of the mcr-1 gene (1%) was detected from E. coli in human (Wang et al., 2017). Tigecycline resistance are mediated by two novel genes, tet(X3) and tet(X4), both of which can significantly reduce the efficacy of tigecycline (He et al., 2019; Sun et al., 2019; Guan et al., 2022). Additionally, bacterial strains carrying the cfr gene encoding 23S rRNA methylase, which is resistant to five classes of antimicrobials, including phenols, lincomides, oxazolidinones, pleuromutilin, and streptomycin A, allowing bacteria to develop MDR (Deng et al., 2014; Tang et al., 2022c).

Whole genome sequencing (WGS) played a vital role in AMR study (Tang et al., 2020b; Peng X. et al., 2022; Li et al., 2022b). We can obtain the tested strains’ AMR and virulence genes by combining them with the antimicrobial sensitivity test (AST). It is helpful to better understand AMR’s development and transmission (Teng et al., 2022). WGS has become an indispensable and reliable tool for revealing the AMR mechanism in global pathogen surveillance (Boolchandani et al., 2019; Tang et al., 2021a; Yang et al., 2022).

In this study, we investigated the prevalence of AMR E. coli in pigs and chickens from animal farms in Eastern China and evaluated the AMR phenotypes, genotypes, virulence genes, and plasmids replicons. This study helps understand the AMR situation and provides a reference to formulate livestock AMR control policies to better protect food safety in China.

Materials and methods

Sample collection and strain isolation

A total of 200 anal swab samples were collected from three cities (Lishui, Jinhua, and Quzhou) located in Zhejiang Province, Eastern China, from March to April 2021. The samples were randomly collected from 110 chickens and 90 pigs in 5 poultry farms and 4 swine farms, respectively (Table 1; Figure 1A). All experiment activities in this study were approved by the Institutional Review Board of Zhejiang Academy of Agricultural Sciences.

Anal swab samples were enriched in 10 ml of buffered peptone solution (BPW, Land Bridge, Beijing, China). After initial pre-enrichment in BPW, 0.1 ml of enriched samples were streaked on MacConkey Agar (Land Bridge, Beijing, China) or Eosin Methylene Blue Agar (Land Bridge, Beijing, China) and incubated at 37°C for 24 h. Only one suspicious colony (round, moist, and show pink color on MacConkey Agar; purple-black color with green metallic sheen on EMB Agar) were selected and further cultured on Luria-Bertani (LB) Agar (Land Bridge, Beijing, China). Bacteria identification was carried out by MALDI-TOF MS. Confirmed isolates were stored at −80°C.

Antimicrobial sensitivity testing

Microbroth dilution method was used (Bio Fosun, Fosun Diagnostics, Shanghai, China) to determine the AMR profile of E. coli isolates (Tang et al., 2022b). The panel of antimicrobial compounds tested included ampicillin (AMP), augmentin (amoxicillin/clavulanic acid, A/C), gentamicin (GEM), tetracycline (TET), spectinomycin (SPT), florfenicol (FFC), sulfisoxazole (SF), trimethoprim/sulfamethoxazole (SXT), cefotin (CEF), ceftazidime (CAZ), ertoloxacin (ENR), ofloxacin (OFL), meropenem (MEM), ampicillin (APR), colistin (CL) and mequinodex (MEQ). The 14 tested antibiotics are grouped into 9 classes (Table 1), including penicillins (AMP and A/C), aminoglycosides (GEM, SPT, and CEF), cephalosporins (CAZ), carbapenems (MEM), sulfonamides (SF and SXT), quinolones (ENR and OFL), and others (APR).
tetracyclines (TET), chloramphenicols (FFC) and polypeptides (CL). The breakpoint for each antimicrobial was from the Clinical and Laboratory Standards Institute (CLSI, 2016:M100-S30). *E. coli* ATCC 25922 was used as quality control.

**Whole genome sequencing and bioinformatics analysis**

The genomic DNA extraction of *E. coli* was performed using a bacterial DNA extraction kit (Generay, Shanghai, China). The whole genome sequencing was performed on the Novaseq 6,000 (Illumina, SanDiego, CA, United States). Clean reads were assembled using SPAdesv3.12.0 (Bankevich et al., 2012). Genome annotation was performed using the NCBI Prokaryotic Genome Annotation Pipeline (Tatusova et al., 2016). ABRicate 1.0.1 tool¹ and VFDB database were applied to predict the virulence genes and AMR genes. Replicons and sequence type (ST) were determined at the Center for Genomic Epidemiology (CGE).² Phylogenetic analysis of the genome and plasmids was performed by kSNP 3.1 software based on the maximum-likelihood method (Gardner et al., 2015). Easyfig 2.2.5 was used for comparative analysis of the plasmids (Sullivan et al., 2011).

Statistical analysis

TBtools was used for clustering heat map analysis of AMR genes, AMR phenotypes, virulence genes, and plasmid replicons (Chen et al., 2020).

Results

Prevalence and AMR of Escherichia coli isolates

A total of 181 E. coli strains were isolated from all 200 anal swab samples with a detection rate of 90.50%. Among them, 96 isolates were from chickens, and 85 isolates were from pigs (Table 1).

E. coli isolates showed the lowest resistance rate to MEM at 2.76%, followed by A/C at 3.31%, CL at 5.52%, and CAZ at 7.18% (Figure 1B). A high resistance rate was shown for five antibiotics in descending order. They were SF (95.03%), SPT (88.40%), SXT (85.64%), AMP (84.53%) and FFC (79.56%). Except for TET with a resistance rate of 59.12%, the resistance rates of E. coli isolates to OFL, ENR, CEF and GEM ranged between 35.0%~40.0% (Figure 2).

The 14 tested antibiotics are grouped into 9 classes (Figure 1B), including penicillins (AMP and A/C), aminoglycosides (GEM, SPT, and CEF), cephalosporins (CAZ), carbapenems (MEM), sulfonamides (SF and SXT), quinolones (ENR and OFL), tetracyclines (TET), chloramphenicol (FFC) and polypeptides (CL). Carbapenems class of antibiotics, which in this study is MEM had the lowest resistance rate. Meanwhile, the sulfonamides class of antibiotics had the highest resistance rate with 181 resistant isolates, of which 172 were resistant to SF.

87.85% of isolates were MDR (Figure 1C, Supplementary Table S1), and the predominant MDR pattern (19.50%, 31/159) was resistance to AMP-SPT-TET-FFC-SF-SXT. Notably, three strains were determined to be resistant to 12 types of antibiotics. The patterns were AMP-A/C-GEM-SPT-TET-FFC-SF-SXT-CEF-CAZ-ENR-OFL and AMP-GEM-SPT-TET-FFC-SF-SXT-CEF-CAZ-ENR-OFL-CL, respectively (Figure 2).

Analysis of genotypes and phenotypes of AMR Escherichia coli isolates

Sixty-five different sequence types (STs) were generated in 181 E. coli isolates (Figure 3), which were further grouped into 16 clonal complexes (CCs) and 38 singletons. Among them, ST10 was most prevalent with 19 isolates (10.50%), followed by ST48 with 13 isolates (7.18%), ST58 and ST162 both with 9 isolates (4.97%).

The plasmid replicon analysis (Figure 4) showed that a total of 40 types of plasmid replicons were detected in all 181 E. coli isolates, of which 107 (59.12%) carried the IncFIB (AP001918) replicon, followed by IncX1 replicon existing in 86 isolates (47.51%), 94.48% (171/181) of the isolates carried 2~6 replicons. Similar plasmid replicon types can be found in different cities and animals, suggesting that plasmids carrying AMR genes may be widely spread through horizontal gene transfer.

As shown in Figure 5, 72 acquired AMR genes were detected in this study, among which mdfr(A) was carried by all isolates. Notably, two isolates carried carbapenem resistance gene blaNDM-5, two isolates carried colistin resistance gene mcr-1, six isolates carried tigecycline resistance gene tet(X4), and eleven isolates carried linezolid resistance gene cfr.

One hundred and sixty-nine virulence genes were found (Figure 6). Ten including entA, entB, entD, entE, entF, fepA, fepC, fepD, fes and ompA were detected in all isolates. The virulence genes carried by the other isolates ranged from 25 to 77. The encoding gene astA of heat-stable enterotoxin1 (East1) was detected in 37.02% (67/181) of the isolates. Three α-hemolysin encoding genes: lyA, lyB and lyD, were present simultaneously in isolates ECJSZ21-06, ECQZZ21-39, and ECJHZ21-15. Thirty-three virulence genes detected here were related to the iron uptake system, and 46 were adhesion-associated genes.

In this study, we found that strains ECJHZ21-07 and ECJHZ21-14 carry the blaNDM-5 gene and have the same genetic context blaNDM-5-bla-trpF-dsbD. Strains ECLSZZ21-04, ECLSZZ21-15, ECQZZ21-02, ECQZZ21-05, ECQZZ21-04, and ECQZZ21-15 contain the tet(X4) gene, which is all adjacent to the estX gene. In the latter two strains, the tet(X4) gene is located in the gene arrangement estX-tet(X4)-ISvsa3 based on better sequencing quality. In addition, we found two strains carrying the mcr-1 gene, which have different genetic environments. The mcr-1-carrying plasmid in strain ECJHZ21-13 is homologous with plasmids pMCR4D3i–3 and pHNSP45 with an IncI2 type; the fragment harboring mcr-1 gene in strain ECQZJ21-13 is homologous with the IncHI2 plasmid (Figure 7).

Strains from different cities can gather on the same branch. As the last line of drugs, the AMR genes mcr-1, blaox genes, and tet(X4) are distributed in different branches, showing different genetic relationships (Figure 8). In the present study, these AMR genes are more likely to be horizontal gene transfer between E. coli strains. In addition, the cfr gene mainly exists in two branches, which may be the clonal transmission (Figure 8).
provide supporting evidence for AMR genes to explain drug resistance. The AMR gene \textit{cfr} mainly existed in two STs, ST2161 and ST162. Two isolates carrying the \textit{bla}NDM-5 were both assigned ST93. Isolates carrying \textit{mcr}-1 belonged to ST2973 (ECJHJ21-13) and ST354 (ECQZJ21-13), respectively (Figure 3). Meanwhile, the isolates carrying \textit{tet}(X4) demonstrated sequence type diversity, ST195, ST48, ST5873 and ST7136 were included.

### Discussion

The AMR of \textit{E. coli} has become a worldwide public health problem (Rutuja et al., 2018). Pigs and poultry products may have a cross infection of AMR \textit{E. coli} during processing and subsequent sale, which increases the risk of transmission and poses a significant threat to the sale of products and people's health (Chang et al., 2020). To understand the current situation of AMR of \textit{E. coli}, we analyzed AMR, MLST and virulence genes of \textit{E. coli} isolated from anal swab samples of pigs and chickens in farms in Lishui, Quzhou and Jinhua, Zhejiang Province, Eastern China. In this study, relatively high AMR rates of FFC (79.56%), SXT (85.64%), SF (95.03%), SPT (88.40%) and AMP (84.53%) were detected that were consistent with the previously published results (Ma et al., 2022; Peng Z. et al., 2022). At the same time, the AMR rates of A/C (3.31%), MEM (2.76%), CL (5.52%) and CAZ (7.18%) were low. CL and MEM are recognized as the last line of defense against gram-negative bacteria (Lin et al., 2022; Wang et al., 2022) and low AMR rates reveal their resistance's effectiveness is decreasing.

Genomic analysis revealed that the \textit{E. coli} isolates harbored various AMR genes, which could be consistent with the AMR phenotype. All \textit{E. coli} isolates contained the AMR gene \textit{mdf}(A), and most of them also carried \textit{tet}(A) (68.51%, 124/181), \textit{floR} (62.98%, 114/181) and \textit{sul}2 (56.35%, 102/181). These genes

*FIGURE 2*  
The MICs of 181 strains. Green indicates sensitivity, yellow indicates intermediary, and red indicates resistance. SF and SXT have no intermediate value, and APR and MEQ have no breakpoint. Ampicillin (AMP), amoxicillin/clavulanic acid (A/C), gentamicin (GEM), tetracycline (TET), spectinomycin (SPT), florfenicol (FFC), sulfisoxazole (SF), trimethoprim/sulfamethoxazole (SXT), ceftriaxone (CEF), ceftazidime (CAZ), enrofloxacin (ENR), ofloxacin (OFL), meropenem (MEM), apramycin (APR), colistin (CL) and mequindox (MEQ).
mediate resistance to tetracycline, chloramphenicol, and sulfonamide antibiotics. These critical AMR genes in E. coli isolates from food animals present a tremendous public health concern. It’s important to mention that the acquired AMR genes in bacterial genomes do not inevitably confer phenotypic resistance and vice versa (Boolchandani et al., 2019; Tang et al., 2022a). Other mechanisms such as SNPs and MDR transporter also significantly contribute to the phenotypic resistance (Boolchandani et al., 2019). The phenotypic confirmation is still essential for validating of AMR profiles. As we found in this study,
only the acquired genes of carbapenem, colistin and tetracycline resistance have the highest consistency with the AMR phenotypes. While other acquired AMR genes can not predict the resistance phenotype of the bacteria very well.

Sixty-five different STs were determined in all *E. coli* isolates. Among them, ST10 accounted for the largest proportion, up to 10.50% (19/181). Next was ST48, and 13 isolates (7.18%) were tested for this ST type. ST10 *E. coli* has been seen repeatedly in
Antibiotic resistance patterns of *E. coli* isolates. Y-axis is the number of isolated strains, and x-axis is the selected AMR genes identified. Green indicates that the isolate is isolated from Quzhou sample, light blue indicates that it is isolated from Lishui, and light yellow indicates that it is isolated from Jinhua. Flesh color indicates that the isolate is isolated from poultry anal swab samples, and cinnabar indicates that it is isolated from pig anal swab samples. Dark green in the small grid indicates the presence of AMR genes, white indicates no, and red indicates the presence of risk AMR genes. The risk AMR genes mentioned here refer to the genes that have been focused on, such as *tet*(X4) (resistant to tigecycline), *mcr-1* (resistant to colistin), *bla*{sub}NDM-5 (meropenem) or *cfr* (resistant to oxazolidinone, amphenicol, lincosamide), which pose a serious threat to public health and safety. Rifamycin (arr-3), Aminoglycoside (aac(3)-Ia, aac(3)-Ib, aac(3)-Id, aac(6′)-Ib-cr), *erm*(B), *mph*(A), *sul*(1), *sul*(2), *sul*(3), *cat*(B3), Beta-lactam (*bla*{sub}CTX-M-14, *bla*{sub}CTX-M-55, *bla*{sub}CTX-M-64, *bla*{sub}CTX-M-65, *bla*{sub}OXA-10, *bla*{sub}OXA-1), Tetracycline (*tet*(A), *tet*(B), *tet*(J), *tet*(M), *tet*(X)).
FIGURE 6
Dendrogram of the hierarchical clustering heat map of isolates and virulence genes. The figure shows the predicted virulence genes factor profile of the studied isolates. Y-axis is the isolate number and x-axis is the selected virulence genes identified. The red color in the small cells indicates virulence genes associated with toxin production, the orange color indicates genes editing other virulence factors, and the white color indicates no virulence expression. Withered grass color indicates isolates isolated from Quzhou samples, yellow indicates isolates from Jinhua, and blue color indicates isolates from Lishui. Incarnadine pink indicates that the isolates were isolated from pig anal swab samples, and bright green indicates that they were isolated from birds.
related pathogenicity studies, with multiple disease outbreaks associated with ST10 in a broiler production unit by testing over 18 months (Bojesen et al., 2022).

Nine of the ST10 *E. coli* isolates detected in our study carried the virulence gene *astA*, which plays an essential role in causing diarrhea and affecting the survival of animals (Meng et al., 2014; Paixão et al., 2016). In recent years, multiple researchers have found that some virulence genes can promote the AMR of bacteria strains (Fu et al., 2022). At the same time, some toxins will be enhanced under the pressure of antibiotics (Wangkheimayum et al., 2022). In our study, the prevalence of *astA* is up to 36.81%. The *astA* gene does not sufficiently lead to disease and is also found in healthy pigs, but when it cooperates with F pili or other virulence genes such as *sta* and *sth*, it will lead to diarrhea and pose a potential threat to food safety. Hemolysin is an important pathogenic factor of pathogenic *E. coli*. It not only plays a role in cracking cells but also promotes cell death by activating typical inflammatory bodies in cells. Hemolysin A (HlyA) toxin is important for triggering cell death in human macrophages (Verma et al., 2019; Gu et al., 2021). Our

---

![Diagram](image-url)
study obtained three isolates carrying encoding genes of three kinds of α-hemolysin, hlyA, hlyB, and hlyD. Here, we would also like to note the proportion of virulence genes associated with the iron uptake system (33/169, 19.53%) and adhesion (46/169, 27.22%). Adhesins are usually a class of glycoprotein or glycolipid biomolecules that are mainly distributed on the surface of bacteria (Berne et al., 2015). The adhesins identified in this study included F1C hairs, K88 hairs, type I hairs, and E. coli common hairs. 

E. coli isolates harbored several kinds of plasmids, with the dominance of IncFIB (AP001918) followed by IncX1. These plasmids have been verified linked to resistance to several antimicrobial classes, including β-lactams, aminoglycosides, sulfonamides, tetracyclines, etc. Our research also showed that these plasmids were carried by isolates originating from chickens and pigs in Zhejiang provinces, indicating that these plasmids could disseminate widely among different hosts (Hu et al., 2016; Tang et al., 2019, 2020a).

Conclusion

In summary, a comprehensive study of AMR and genomic characterization of E. coli isolated from pigs and chickens anal swab samples in Eastern China was conducted. A high prevalence of MDR E. coli and many virulence determinants in the isolates posed a potential risk to food safety. This is a significant warning for public health safety in Zhejiang Province. It is essential to continue monitoring the MDR E. coli and implement antimicrobial stewardship programs for rational use of essential antimicrobials in animal farms to improve food safety and prevent the emergence of MDR bacteria.
