Recent analyses of population data reveal that obesity rates continue to rise, and are projected to reach unprecedented levels over the next decade. Despite concerted efforts to impede obesity progression, as of today, weight loss and weight maintenance strategies remain at best partially successful endeavours. Regardless of the observation that weight loss strategies can produce significant weight loss and substantial improvements of the determinants of the metabolic risk profile, it is clear that actual weight loss tends to be lower than the anticipated weight loss, and most individuals who achieve weight loss will likely regain some weight and even overshoot their pre-intervention body weight. As such, an improved understanding of the factors that contribute to lower than expected weight loss, and poor weight maintenance would improve the effectiveness of weight loss interventions.

Increasing physical activity participation is frequently recommended as a method of improving weight management for its recognized ability to positively impact metabolic and psychological health. Despite these valuable outcomes, weight loss is often much less than expected, when exercise is employed as the sole means of intervention at least as far as effectiveness are concerned. This suggests that amongst other things, compensatory responses (i.e. increase energy intake and/or reduced non-structured physical activity) occur which undermine the weight loss. It is possible that these compensatory responses are driven at least in part by the observations that weight loss and exercise increase appetite and the reinforcing value of foods, and that exercise has also been shown to decrease non-exercise energy expenditure. Exercise can also lead to beneficial changes in ectopic fat storage even in the absence of major changes in body weight, an outcome that may be easily overlooked with traditional markers of weight loss success.
In this special call for papers we sought manuscripts related to exercise induced weight loss with a particular emphasis on the effects of exercise on ectopic fat mobilization, non-exercise activity thermogenesis and appetite regulation. This Update on Exercise and Weight Control contains 14 original manuscripts and 5 review articles that cover a wide-array of methodologies, populations, training modalities but that all share the common feature of dealing with different aspects of physical activity/exercise and weight management.

Five comprehensive reviews appear in this special issue. In the paper by Strasser et al. 16, clear recommendations on the use of resistance training for the treatment of obesity were derived from available literature. Nantel et al. 17 present an interesting overview of the biomechanical considerations related to physical activity and obesity whereas the paper by Boutcher 18 provides arguments for increasing exercise intensity to improve the effects of exercise on fat mobilization and metabolic health. The fourth review article by Chaput et al. 19 presents a series of studies that provide evidence in support of an important role of physical activity in body weight control. In the last of the reviews, the authors surveyed the literature on cognitive-behavioural strategies to increase the adherence to exercise in hopes of improving weight management 20.

The special issue included three original research communications that dealt directly with eating behaviour and appetite. Results presented in the paper by Finlayson et al. 21, highlight the role of hedonic processes and in particular, increased food reward as a contributor to reduced fat loss in response to exercise. The paper by Riou et al. 22 presents evidence that the relationship between eating behaviour traits and adiposity may well be modulated by the level of physical activity. In
the third paper, King et al.\textsuperscript{23} report that moderate intensity swimming increases appetite, but that this effect is not related to circulating ghrelin levels.

Two additional research communications are directly in line with this special call for papers. The first one presents results that support the notion that total physical activity energy expenditure may actually be lower on days where structured exercise is performed in obese women; an effect that seems to be accentuated for high intensity exercise\textsuperscript{24}. Results from an exercise intervention with or without a weight loss component showed that muscle fat infiltration decreased significantly in both groups but to a much greater extent in the exercisers that also experienced weight loss\textsuperscript{25}.

This special issue also contains 4 original research communications that relate the effects of exercise and weight control on psychological outcomes. In the paper by Vieira et al.\textsuperscript{26}, the results support that self-determined motivation for exercise seems to positively impact some psychological variables; an effect that is independent of weight change during the weight loss intervention. Amongst other things, the paper by Napolitano et al.\textsuperscript{27} highlighted that the success of long-term weight loss was related to improved self-efficacy whereas weight gain was associated to depressed mood. Results by Green et al.\textsuperscript{28} papers published in this issue show that exercise does not exert the same effects on quality of life in individuals with type 2 diabetes. The last paper in this group investigated the effects of a 12-week home-based physical activity and nutrition intervention in seniors. The program was successful at increasing walking time which was partly attributable to increased awareness of health and well-being\textsuperscript{29}. 
Three original papers related to children appear in this special issue of the Journal of Obesity. In one of these papers, the authors tested the utility of accelerometers to assess physical activity in children attending an obesity treatment intervention. The results highlight the possibility that accelerometers may underestimate physical activity in this population \(^3^0\). Results from another study reported different physical activity patterns measured with accelerometry between lean and obese children \(^3^1\). In the last paper, an after-school physical activity program was shown to improve body composition and fitness in African-American boys who attended at least 3 times per week \(^3^2\).

The last two communications relate to levels of physical activity. In the first of these 2 papers, an 8-week Latin dance intervention was shown to increase physical activity in overweight women \(^3^3\). Results of the last study in this issue suggest that estimates of physical activity levels vary by BMI categories, which may lead to misclassify adults with type 2 diabetes as being sufficiently active \(^3^4\).

In summary, the original research combined with the review papers in this special issue of the Journal of Obesity highlight the fact that research on exercise and body weight control is evolving. The rich diversity of research questions around this topic will, in time, help us understand the multifaceted aspects of the effects of exercise on the management of body weight and the complications associated with increased adiposity.
