ABSTRACT. Southwestern Atlantic/eastern South American records of the Kerguelen Petrel *Lugensa brevirostris* are scarce, comprised only of specimens found dead on the coast. Here we present a review of records known from this region, including a novel record based on a specimen stranded at Arraial do Cabo, Rio de Janeiro state, Brazil. Additionally, we draw the attention of ornithologists and observers to problems of specimen identification, even in museums, when one needs to separate Kerguelen Petrel from dark-morph Herald Petrel *Pterodroma arminjoniana* or other dark-plumaged gadfly petrels of the genus *Pterodroma*. For identification of museum specimens, we recommend the use of an osteological character state, which allows unequivocal identification of Kerguelen Petrels, namely the wide and fenestrated fossa glandulae nasalis of the frontal bone.

KEY-WORDS: diagnostic characters, osteological characteristics, petrel, Procellariidae, review, South America.
Specimen records in the southwestern Atlantic and a new Brazilian record

Escalante (1980) reported the first specimen for the whole southwestern Atlantic coast of South America, a stranded individual found in July 1973 at Canelones, Uruguay (Table 1). This seems to be the only Uruguayan specimen, and there also seem to be no records at sea. Kerguelen Petrels are much more frequent southward, over the Patagonian Shelf (Orgeira 2001), and around the Falkland/Malvinas Islands (Thurston 1982; Bourne & Curtis 1985; White et al. 1999), particularly over offshore waters, as well as between southern South America and Antarctica (Orgeira et al. 2013). However, to the best of our knowledge, there are no records of stranded specimens along the Argentinean coast (Mazar-Barnett & Pearman 2001).

There are only three published records of Kerguelen Petrel in Brazil, the first one being a stranded specimen from Bahia (September 1985); the second, a bird found in Rio Grande do Sul state in October 1986 (Figure 1; see below); and the third, a male found in Arembepe, Bahia, in July 1994 (Table 1). To the best of our knowledge, no at-sea records off the Brazilian coast exist.

On 28 September 2012, during activities of a beach monitoring program of the Campos and Espírito Santo basins (Projeto Monitoramento de Praias das Bacias de Campos e Espírito Santo – PMP-BC/ES) a dead specimen of an all brown-gray, mid-sized petrel was found at the Monte Alto beach (22°56'S, 42°09'W), municipality of Arraial do Cabo, Rio de Janeiro state, Brazil. Measurements (in mm) of this specimen are as follows: total length 350; exposed culmen 27; wing chord 260; tail 138; tarsus 37.6; middle toe with claw 48.9; middle toe without claw 43.9.

It had the diagnostic whitish leading edge from the carpal joint to the body (Figure 2), which characterizes Kerguelen Petrels (Marchant & Higgins 1990), but it was a relatively large bird, fitting in both the lower range of biometric data of Trindade Petrels (Luigi et al. 2009), and in the upper range of Kerguelen Petrels (e.g., Onley & Scofield 2007), which makes plumage- and biometric-based identification difficult. This difficulty is especially true if we consider that light, intermediate, and dark morphs of Trindade Petrels could exhibit a whitish leading edge from the carpal joint to the body (Figure 3; Flood & Fisher 2013:73, 76). This suggests that other characters should be investigated to allow an unequivocal identification. Thus, in the following section, we explore cranial characteristics that allowed unambiguous identification of the Arraial do Cabo specimen as a Kerguelen Petrel.

### TABLE 1. All known specimen records of Kerguelen Petrels *Lugensa brevirostris* from the southwestern Atlantic Ocean. MNRJ – Museu Nacional, Rio de Janeiro; CAFURG – Coleção de Aves da FURG; RG – Rolf Grantsau private collection; MNHN – Museo Nacional de Historia Natural de Montevideo.

| Specimen | Place                  | Geographic coordinates | Date         | Features used in identification                  | Source                          |
|----------|------------------------|------------------------|--------------|--------------------------------------------------|---------------------------------|
| *MNRJ 35237* | Salvador, Bahia, Brazil | ca. 12°59'S, 38°31'W   | September 1985 | Plumage and measurements                          | Teixeira et al. (1988)          |
| CAFURG 311 | Cassino Beach, Rio Grande do Sul, Brazil | 32°11'S, 52°10'W | 1 October 1986 | Plumage and measurements; skull osteology (this study only) | Vooren & Fernandes (1989); this study |
| *RG 9480* | Arembepe, Bahia, Brazil | 12°43'29''S, 38°10'45''W | 15 July 1994  | Plumage and measurements                          | Lima et al. (2004)              |
| CAFURG 450 | Arraial do Cabo, Rio de Janeiro, Brazil | 22°56'S, 42°09'W | 28 September 2012 | Plumage and measurements; skull osteology         | This study                      |
| *MNHN 04142* | La Floresta, Canelones, Uruguay | 34°46'S, 55°37'W | 25 July 1973  | Cuello (1975), misidentified as *P. macroptera*, corrected by Escalante (1980). See pictures in Jiménez et al. (2012). |                                  |

*Specimen not examined for the present study.*
The Kerguelen Petrel *Lugensa brevirostris* in the Southwestern Atlantic Ocean, with notes on osteology and plumage-based identification

Giovanni N. Maurício, Jonathas Barreto, and Leandro Bugoni

**FIGURE 1.** Skull of a *Lugensa brevirostris* specimen (CAFURG 311) obtained at Cassino Beach, Rio Grande do Sul, Brazil, on 1 October 1986. This is the only specimen of *L. brevirostris* from this Brazilian state published to date. Identification is now corroborated by the observation of the characteristic fenestrated fossa glandulae nasalis (the arrow indicates the rostral fenestra; see text).

**FIGURE 2.** Kerguelen Petrel *Lugensa brevirostris* stranded in Rio de Janeiro in September 2012 (CAFURG 450), showing the whitish leading edge on underwing (arrow).
Osteology-based identification of gadfly petrels

Imber (1985), in part based on limited osteological comparisons conducted by Harper (1973), called attention to a condition of the skull distinguishing unequivocally Kerguelen Petrel from any Pterodroma species, namely, the lateral extension of the inter-orbital region that covers most of the orbit. Therefore, given the identification problems explained above, the Arraial do Cabo specimen was prepared as a skeleton (Coleção de Aves da Universidade Federal do Rio Grande - CAFURG 450), except for a wing which was left completely feathered to document the wing pattern that helps species identification by plumage (Onley & Scofield 2007). The skeleton was prepared by maceration and hand-cleaning soft tissue from bone (Alvarenga 1992). It was immediately evident that the orbit of the specimen was mostly covered dorsally by a supra-orbital bony extension of the os frontale, forming a wide fossa glandulae nasalis, a condition in great contrast to that observed in members of the genus Pterodroma (Harper 1973; Imber 1985; Figure 4). Additionally, each fossa seen in Lugensa skulls bears a large rostral fenestra (Figures 1 and 4) not seen in other procellariid genera (Imber 1985; this study), suggesting it represents an autapomorphy for this taxon. Imber (1985) stated that Lugensa has a “unique fenestrated extension of the skull lateral to the supra-orbital gland”, but some very small, caudal fenestrae similar to those seen in Lugensa are present in some specimens of other presumably related genera (Thalassoica, Fulmarus; Imber 1985, Shearwater.nl. 2013 [http://www.shearwater.nl/?file=kop1.php]), thus indicating that only the rostral fenestra is fully diagnostic of, and autapomorphic for, the genus (see also Mayr & Smith [2012] for a comprehensive phylogenetic analysis of procellariiforms using osteological characters). Preceding Imber (1985), when comparing skulls of Kerguelen and Soft-plumaged petrels, Harper (1973) highlighted the larger width of the lateral edges housing the supraorbital depressions, whose “ledges … are characteristically crenated, fenestrated and ledged along their perimeter to a degree not shown in Soft-plumaged Petrel”.

Except for Harper (1973) and Imber (1985), to the best of our knowledge, no other researcher has used the osteological character states mentioned above to identify Lugensa specimens (Cuello 1975; Escalante 1980; Teixeira et al. 1988; Vooren & Fernandes 1989; Lima et al. 2004; Jiménez et al. 2012), thus overlooking the opportunity to confirm identification using fully diagnostic and easy-to-see morphological features. Even if one is interested in producing a traditional museum specimen, it is possible to check the condition of the os frontale – i.e., if matching or not the Lugensa type – by inverting the skin up to the base of the bill during taxidermy and by a simple removal of the soft tissue of the nasal gland. For old museum skins, or those specimens recently prepared, ordinary x-ray radiography could be an option.

The only specimen of Kerguelen Petrel from Rio Grande do Sul state published to date is that mentioned by Vooren & Fernandes (1989), which is deposited at CAFURG under the catalogue number 311. This specimen was not prepared as a skin, being simply wholly dried and preserved in the collection. Overall, it is in poor condition, with exposed bones in several parts of the body. As its skull was greatly exposed, a simple removal of the dried tissue over the salt gland allowed us to examine the condition of the fossa glandulae nasalis: the Rio Grande do Sul bird proved to represent a typical L. brevirostris specimen by presenting the unique fenestrated extension of the skull lateral to the nasal

FIGURE 3. Trindade Petrels Pterodroma arminjoniana from Trindade Island, Brazil, illustrating the whitish trailing edge on underwing, in both the a) light and b) intermediate morphs (arrows).

...gland (Figure 1). Although plumage and measurements (see Vooren & Fernandes 1989) of this specimen are apparently sufficient to determine its specific identity with certainty, the observation of the condition of the *fossa glandulae nasalis* prevents any possible future dispute regarding its identification.

**FiGurE 4.** Skulls of Kerguelen Petrel *Lugensa brevirostris* (above; CAFURG 450) and Atlantic Petrel *Pterodroma incerta* (below; CAFURG 603) in dorsal view. Note the wide, fenestrated *fossa glandulae nasalis* (F) of the former and the contrastingly narrow fossa of the latter. The condition seen in Kerguelen Petrel is fully diagnostic in comparison with any other procellariform taxon.

**Concluding remarks**

The status of Kerguelen Petrels in the southwestern Atlantic Ocean seems to be similar to the Great-winged Petrel. Both species are rarely found stranded on the beach along the southwestern Atlantic coast (Bugoni 2006; Jiménez *et al.* 2012), and are nearly absent at sea (Bugoni *et al.* 2008; Jiménez *et al.* 2011), despite both species being common southeastward, *e.g.*, in the Southern Ocean at about 60°S, 0°W (Joiris *et al.* 2013; Commins *et al.* 2014). All five Kerguelen Petrels records on the coast of Brazil and Uruguay are from July to early October, coinciding with the pre-breeding or pre-laying exodus, as eggs are laid in October (Elliott 1957; Shirihai 2007).

Examination of the condition of the *fossa glandulae nasalis* may be the only way to identify decomposed specimens found on beaches, and such possibility may provide more realistic information on the occurrence of *L. brevirostris* in a given region. Finally, we suggest that any dispute regarding identity of supposed *Lugensa* specimens might be solved by radiographing skulls to determine the condition of the fossa.

**ACKNOWLEDGEMENTS**
