SECTION 2 – ANSWER

Case

The case previously presented is one of a 28-year-old female with a rapidly growing mass over the volar aspect of her right thumb, in close contact with the flexor pollicis longus (FPL) tendon at the level of the 1st metacarpophalangeal joint, measuring approximately 8.2 mm × 3.3 mm × 6.6 mm in size. It showed no hypervascularity, was noncompressible, with hypoechoic homogeneous echotexture, and had mild posterior acoustic enhancement, smooth contours, and no evidence of bony involvement [Figures 1-4 and Videos 1, 2].

The dynamic ultrasound (US) allowed demonstration that there was no movement of the mass with FPL contraction.

Interpretation

The differential diagnosis before the US was performed included ganglion cyst and giant cell tumor of the tendon sheath (GCTTS). Given the above-mentioned characteristics, the most likely diagnosis after the US was a giant cell tumor of the FPL tendon sheath. As the patient had noticed a rapid growth, she was sent directly to surgery for excision.

The pathology confirmed that tumor was a giant cell tumor of the tendon sheath, without any signs of malignancy. The patient evolved well afterward, without any surgical complications.

Discussion

GCTTS is the second most common mass of the hand, after ganglion cyst.[1] It is benign in nature[1] and is composed predominantly of four types of cells, namely synovial cell, multinucleated giant cell, foam cell, and histiocyte-like cell.[2]

Many terms have been utilized to refer to it since it was first described in 1852 as fibrous xanthoma by Chassaignac[3] and localized nodular tenosynovitis, pigmented villonodular proliferative synovitis, sclerosing hemangioma, benign synovioma, proliferative synovitis, xanthoma, xanthogranuloma, xanthosarcoma, myeloid endotheioma, fibrohemosideric sarcoma, giant cell fibrohemangioma, pigmented villonodular tenosynovitis, fibroma, myeloxanthoma, and fibrous histiocytoma.[1,3-5]

A study by Middleton et al. has described the sonographic findings of GCTTS.[6] In their retrospective patient population of 12 (8 females and 4 males), presentation was most often one of a painless mass (10/12), involving the flexor tendon sheath (10/12), with cases involving all digits of the hand.[6] All tumors were hypoechoic, most of them were homogeneous (10/12) with internal vascularity (11/12), and posterior acoustic enhancement was seen in four of the 12 patients. Importantly, all the lesions were in contact with a tendon sheath, and they never moved as the digit was flexed or extended, as the tumor arises from the sheath and not the tendon itself.[6]

If the ultrasonographer is in suspicion that, if the lesion is cystic or not (GCTTS might be hypoechoic with posterior acoustic enhancement), the presence of internal vascularity can help confirm the solid nature of the mass.

In the case described, no hypervascularity was noted, which might be possible even if the contrary is more typical, but technical factors can also come into play, such as Doppler sensitivity and pressure applied by the US probe which might compress small vessels.

A study by Wang et al. proposed to use US as the initial method to assess a suspected GCTTS.[7] Nevertheless, although US appearance is often highly suggestive, definitive diagnosis can only be made by tissue pathology.

One of the distinctive features with ganglion cyst is that GCTTS is not amenable to aspiration or steroid injection. Marginal
