Abstract

Accurate fire emissions inventories are crucial to predict the impacts of wildland fires on air quality and atmospheric composition. Two traditional approaches are widely used to calculate fire emissions: a satellite-based top-down approach and a fuels-based bottom-up approach. However, these methods often considerably disagree on the amount of particulate mass emitted from fires. Previously available observational datasets tended to be sparse, and lacked the statistics needed to resolve these methodological discrepancies. Here, we leverage the extensive and comprehensive airborne in situ and remote sensing measurements of smoke plumes from the recent Fire Influence on Regional to Global Environments and Air Quality (FIREX-AQ) campaign to statistically assess the skill of the two traditional approaches. We use detailed campaign observations to calculate and compare emission rates at an exceptionally high resolution using three separate approaches: top-down, bottom-up, and a novel approach based entirely on integrated airborne in situ measurements. We then compute the daily average of these high-resolution estimates and compare with estimates from lower resolution, global top-down and bottom-up inventories. We uncover strong, linear relationships between all of the high-resolution emission rate estimates in aggregate, however no single approach is capable of capturing the emission characteristics of every fire. Global inventory emission rate estimates exhibited weaker correlations with the high-resolution approaches and displayed evidence of systematic bias. The disparity between the low resolution global inventories and the high resolution approaches is likely caused by high levels of uncertainty in essential variables used in bottom-up inventories and imperfect assumptions in top-down inventories.
Reconciling Assumptions in Bottom-up and Top-down Approaches for Estimating Aerosol Emission Rates from Wildland Fires using Observations from FIREX-AQ

Key Points:

• In situ measurements of wildland fire smoke plumes provide emission rates for evaluating emissions inventories at unprecedented resolution
• Fire emissions inventories struggle to capture the emissions rate characteristics of individual fires but may perform well in the aggregate
• Bottom-up inventories suffer from major uncertainty in key variables, while top-down inventories may have bias from imperfect assumptions
Abstract

Accurate fire emissions inventories are crucial to predict the impacts of wildland fires on air quality and atmospheric composition. Two traditional approaches are widely used to calculate fire emissions: a satellite-based top-down approach and a fuels-based bottom-up approach. However, these methods often considerably disagree on the amount of particulate mass emitted from fires. Previously available observational datasets tended to be sparse, and lacked the statistics needed to resolve these methodological discrepancies. Here, we leverage the extensive and comprehensive airborne in situ and remote sensing measurements of smoke plumes from the recent Fire Influence on Regional to Global Environments and Air Quality (FIREX-AQ) campaign to statistically assess the skill of the two traditional approaches. We use detailed campaign observations to calculate and compare emission rates at an exceptionally high resolution using three separate approaches: top-down, bottom-up, and a novel approach based entirely on integrated airborne in situ measurements. We then compute the daily average of these high-resolution estimates and compare with estimates from lower resolution, global top-down and bottom-up inventories. We uncover strong, linear relationships between all of the high-resolution emission rate estimates in aggregate, however no single approach is capable of capturing the emission characteristics of every fire. Global inventory emission rate estimates exhibited weaker correlations with the high-resolution approaches and displayed evidence of systematic bias. The disparity between the low resolution global inventories and the high resolution approaches is likely caused by high levels of uncertainty in essential variables used in bottom-up inventories and imperfect assumptions in top-down inventories.

Plain Language Summary

Smoke emitted by wildland fires is dangerous to human health and contributes to climate change. To predict and evaluate the impacts of fires, we need to know how much smoke is emitted into the atmosphere. There are two state-of-the-art methods used to estimate the mass of smoke emitted by fires, but they often disagree. In this study, we use unusually detailed measurements collected using an aircraft that flew within wildland fire smoke plumes to calculate the amount of smoke emitted from fires in the Western United States. We compare emission rates derived from the exceptionally high spatial and temporal resolution approach to the two traditional, lower resolution approaches to understand why they sometimes diverge.

1 Introduction

Wildland fires can be dangerous, destructive forces of nature that degrade air quality and threaten human health and infrastructure (Larsen et al., 2018). However, fires are also a naturally occurring disturbance needed to maintain the health and biodiversity of many ecosystems (Goldammer et al., 2008; Weaver, 1974). In the Western United States, the natural fire cycle has been completely disrupted and distorted by human interference (Fusco et al., 2016; Harvey, 2016), where large increases in fire size and occurrence are transpiring because of a buildup of fuels caused by historically excessive fire suppression, increased settlement in the wildland urban interface, and more favorable fire weather conditions (Abatzoglou & Williams, 2016; Dennison et al., 2014; Mell et al., 2010; Stavros et al., 2014; Stephens & Ruth, 2005; Theobald & Romme, 2007; Westerling et al., 2003). There is a need for balance between reducing the
hazards of wildland fires while maintaining forest health under the influence of a changing climate.

Unless we can better understand and predict the deleterious impacts of wildland fire smoke emissions on air quality and human health, it will be nearly impossible for society to respond and adapt to this evolving and complex system. Informed land management policy that utilizes prescribed fires to reduce fuel buildup and reinvigorate ecosystems in order to ultimately minimize smoke exposure for downwind communities necessitates the ability to quantify the composition, magnitude, and transport of smoke (Noss et al., 2006; Schweizer et al., 2018). In the case of accidental or uncontrolled wildfires, the capability to accurately predict smoke transport is necessary to alert sensitive populations and mitigate the overall impact of smoke on human health (Larkin et al., 2009; McKenzie et al., 2006). Atmospheric models rely entirely on geospatial databases of fire locations and estimated emissions (so-called fire emissions inventories) to represent the contribution of fire emissions to downwind atmospheric composition (Wiedinmyer et al., 2006). Two distinct approaches are traditionally used to create these emissions inventories: a fuels-based bottom-up approach and a satellite-based top-down approach (Seiler & Crutzen, 1980; Wooster et al., 2005).

The bottom-up approach calculates the mass of carbon emitted by a fire as the product of burned area, fuel mass per unit area, the carbon fraction of fuel, and combustion completeness (Seiler & Crutzen, 1980). This approach, also known as the carbon mass balance method, operates under the explicit assumption that all burnt biomass carbon is volatilized and emitted to the atmosphere (Ward & Radke, 1993). Although a fuels-based approach is the key feature of bottom-up algorithms, most also rely on remote sensing observations from satellite sensors such as the Moderate Resolution Imaging Spectroradiometer (MODIS) or Visible Infrared Imaging Radiometer Suite (VIIRS) to determine burned area. Burned area can be calculated using active fire detections, by assuming the entire landscape captured in the resolution of a single satellite pixel burned, or burned area can be taken directly from higher level data products (Kaiser et al., 2012; van der Werf et al., 2017; Wiedinmyer et al., 2011). Fuel mass per unit area is often derived from either a biogeochemical model initialized with satellite observations and/or from labor intensive fuel databases of fuel type and loading (McKenzie et al., 2012; Pettinari & Chuvieco, 2016; Sandberg et al., 2001; van der Werf et al., 2017). Fuel carbon content is often assumed based on laboratory measurements from previous studies or estimated using the sum of CO₂, CO, and CH₄ emission factors (Akagi et al., 2011; McMeeking et al., 2009; Santín et al., 2015; Susott et al., 1991; van der Werf et al., 2017; Yokelson et al., 1997). Combustion completeness is calculated as a function of changes in visual landscape characteristics, reduction in fuel moisture, increase in summer land surface temperature, tree cover, and/or daily fire weather indices (Kaiser et al., 2012; van der Werf et al., 2017; Wiedinmyer et al., 2011).

The bottom-up approach requires an ecosystem-specific emission factor to convert total carbon mass emissions to emissions of a particular trace gas or aerosol species (Akagi et al., 2011; Andreea & Merlet, 2001). Emission factors are often attained from compilations of previous studies categorized by fuel or vegetation type and show a wide range of natural variability depending on the exact composition of fuel being burned and combustion conditions. Certain species, including many volatile organic compounds (VOCs) and aerosols, rapidly evolve in the atmosphere following emission, which necessitates emission factor estimates derived only from measurements of young, fresh smoke. There are numerous particulate mass (PM) emission factors published from ground and laboratory based studies, however in situ
airborne measurements of PM emission factors for Western US wildland fires are particularly scarce (Akagi et al., 2011).

The top-down approach follows from Wooster et al. (2005), who showed that the burning of dry vegetation yields the same amount of energy, regardless of fuel type. Top-down inventories assume fire radiative power (FRP) observations from satellite remote sensing can be used as a direct measurement of the amount of biomass consumed in a fire in an effort to bypass the latency and uncertainty associated with variables required in bottom-up style inventories (Ichoku & Kaufman, 2005). In the top-down approach, FRP is multiplied by a predetermined coefficient, known as a smoke emission coefficient (C_e), to calculate fire emission rates of PM. Smoke emission coefficients are constants derived for individual ecosystems by combining multiple years of aerosol optical depth (AOD) remote sensing observations with a mass extinction efficiency (MEE), a constant that relates particle extinction to particle mass (Giglio et al., 2006; Ichoku et al., 2008; Kaiser et al., 2012). Ichoku et al. (2008) demonstrated that the relationship between fire radiative energy (FRE), or temporally integrated FRP, and the emission rate of PM could be quantified using AOD during a controlled laboratory-based experiment. The smoke emission coefficient determined from the laboratory-based experiment agrees with independent estimates derived from satellite measurements of FRP and AOD measured over large-scale wildfires, which leads to the assumption that this approach can be extrapolated to global scale observations of FRP and AOD.

There are dozens of top-down and bottom-up emissions inventories available for use in atmospheric transport models. These inventories encompass wide ranges of spatial and temporal scales and can be used to account for hundreds of individual pollutants emitted by fires (Darmenov & da Silva, 2013; Ichoku & Ellison, 2014; Kaiser et al., 2009; Mota & Wooster, 2018; van der Werf et al., 2017; Wiedinmyer et al., 2011). The choice of which inventory to use in modeling applications is crucial, because different fire emissions inventories can profoundly disagree on the magnitude, composition, and temporal variability of fire emissions, especially PM (Carter et al., 2020; Larkin et al., 2014; Liu et al., 2020; Pan et al., 2020). The underlying cause of the disagreement is difficult to isolate, but could be an artifact of the various assumptions used in each inventory. Most global emissions inventories are plagued with high levels of uncertainty stemming from the individual datasets used to calculate emissions, which further complicates the ability to isolate the cause of the discrepancies among inventories (French et al., 2004; Urbanski et al., 2011; Wiedinmyer et al., 2011). For example, the detection and quantification of active fire locations, FRP, and AOD using satellite remote sensing suffers from the obscuration of the land surface by clouds or thick smoke, limited spatiotemporal coverage or resolution, and instrument detection limits.

It is fundamentally challenging to correctly quantify biomass burning emissions due to the highly variable composition and structure of the fuels that fires consume, and because fires can rapidly change their behavior in response to dynamic meteorological or environmental conditions (Kennedy et al., 2020; Liu, 2004; Schultz et al., 2008). The datasets used in global fire emissions inventories attempt to capture these dynamics, but they often lack the spatial and temporal resolution needed to fully encapsulate all of the individual components that influence emissions. Intensive in situ measurements of smoke from the joint NASA/NOAA Fire Influence on Regional to Global Environments and Air Quality (FIREX-AQ) campaign that was conducted during the summer of 2019 provide a unique opportunity to evaluate the assumptions and uncertainties in both top-down and bottom-up approaches for calculating fire emissions. During FIREX-AQ, the NASA DC-8 aircraft was outfitted with a comprehensive instrument payload
that sampled smoke plumes from Western US wildland fires and Southeastern US prescribed and
agricultural fires. The plume sampling strategy for the western portion of the campaign consisted
of an above-plume, longitudinal run along the entire length of the plume to allow for nadir-
pointing remote sensing of the smoke followed by a set of plume transects perpendicular to the
direction of smoke transport where the aircraft sampled the plume in situ during a series of
sequentially-downwind, cross-sectional passes (Wiggins et al., 2020).

Measurements collected during FIREX-AQ provide the opportunity for a rare direct
collection and evaluation of the traditional, lower resolution approaches to calculate fire
emissions at an unusually high spatial and temporal resolution. In this study, we calculate fire
total carbon and total PM emission rates from Western US wildland fires sampled during
FIREX-AQ using a novel, independent approach based on in situ smoke plume measurements.
Here, we integrate in situ trace gas and aerosol measurements with information on plume
thickness gleaned from airborne High-Spectral Resolution Lidar (HSRL) measurements to
calculate emission rates. Although this new approach is subject to its own uncertainties and
sources of error, we assume emission rate estimates derived from this approach are as close to
accurate as we can realistically achieve, because they are based on in situ measurements, and
their calculation doesn’t require as many strong assumptions as the more traditional approaches.
We further capitalize on FIREX-AQ data to calculate fire emission rates using a high-resolution
top-down approach and a high-resolution bottom-up approach. The high-resolution top-down
approach (referred to as HSRL-GOES) uses airborne HSRL measurements of particle extinction
instead of satellite observations of AOD, and the high-resolution bottom-up approach (referred to
as Fuel2Fire) uses carbon emission estimates from the newly-developed Fuel2Fire carbon
emissions inventory that has been developed and optimized specifically to estimate emissions
from the fires sampled during FIREX-AQ. We also obtain emission rates from a traditional
bottom-up fire emissions inventory, Global Fire Emissions Database (GFED4.1s), and a
traditional top-down fire emissions inventory, Fire Energetics and Emissions Research
(FEERv1.0). GFED and FEER have much lower temporal and spatial resolutions (3-hr/daily,
0.25° and daily, 0.1° respectively) compared to the three high-resolution FIREX-AQ based
approaches. We evaluate the performance of GFED and FEER, along with the high-resolution
approaches, against the in situ measurement based approach to investigate potential bias and
assess the validity of the assumptions unique to each approach (Figure 1). We also investigate
and quantify uncertainty for all of the approaches used to calculate emission rates in this study.
The goal of this paper is to understand how the estimates of total carbon and PM emission rates
from traditional, lower resolution methods compare to the high-resolution estimates available for
the fires sampled during the FIREX-AQ campaign. The results of this analysis should be of keen
interest for the global wildfire emissions inventory community as well as atmospheric scientists
seeking to use airborne observations to constrain wildland fire aerosol emissions.

2 Methods

2.1 Emission Rate Estimates from Global Inventories

2.1.1 GFED4.1s (Low-Resolution Bottom-up)

GFED is a global fire emissions inventory that internally calculates carbon emission rates
using a traditional bottom-up approach as follows
where $E_C$ is the carbon mass emission rate, $BA$ is the burned area, $FL$ is the fuel mass loading per area, $CC$ is the combustion completeness (expressed as a percent), and $F_C$ is the mass fraction of carbon in the fuel (van der Werf et al., 2017). GFED obtains burned area estimates from MODIS (MCD64A1), fuel loading and combustion completeness are derived from the Carnegie-Ames-Stanford Approach (CASA) biogeochemical model, and carbon mass fraction is defined per ecosystem from compilations of previous studies (Akagi et al., 2011; Andreae & Merlet, 2001; van der Werf et al., 2017).

To represent a traditional bottom-up approach, we use daily average carbon emission rates per area from GFED4.1s (https://www.globalfiredata.org/) to calculate daily average PM emission rates ($E_{PM}$) for the western fires sampled during FIREX-AQ as follows

$$E_{PM} = EF_{PM} \times \sum \frac{E_C \times A_{P,GFED}}{F_C}$$

where $EF_{PM}$ is the total particulate matter mass emission factor suggested by GFED for temperate forests (17.6 gPM kg-biomass consumed$^{-1}$), $E_C$ is the area-normalized daily carbon emissions in each GFED pixel, $A_{P,GFED}$ is the GFED pixel area ($0.25^\circ \times 0.25^\circ$), and the summation is carried out over all GFED pixels within $0.25^\circ$ of the centroid of the final United States Geological Survey Geospatial Multi-Agency Coordination (GeoMAC) fire perimeter for each fire. In Equation 2, we use the $F_C$ suggested by GFED for temperate forests (0.489 kgC kg-biomass consumed$^{-1}$). The use of ecosystem level constant values for $EF_{PM}$ and $F_C$ is intended to provide good results in aggregate on the regional-to-global scales required by models, although individual fires will deviate from these specifications. GFED data is provided on a daily and a 3-hr basis in UTC time, and here we use the daily product. We convert from UTC time to local time by assuming daily emissions (local time) are equal to 75% of the emissions from the day a given fire was sampled by the DC-8 aircraft (local time) plus 25% of the emissions from the day after (local time).

We estimate relative uncertainty in $E_C$ and $E_{PM}$ estimates derived from GFED by propagating uncertainty through equation 1 and equation 2. For equation 1, we assume the following relative uncertainties: $BA = 44\%$, $FL = 111\%$, $CC = 11\%$, and $F_C = 10\%$. For equation 2, we assume $EF_{PM}$ has a relative uncertainty of 36\% and $E_C$ has a relative uncertainty calculated by propagating uncertainty through equation 1. We obtain the relative uncertainty in the BA product used by GFED from an analysis of MODIS burned area by Giglio et al. (2018). $FL$ and $CC$ relative uncertainty are derived by taking the standard deviation divided by the average for all field measurements of Western US fuels as compiled by van Leeuwen et al. (2014) and updated by van der Werf et al. (2017). $F_C$ relative uncertainty is defined as the standard deviation divided by the average in $F_C$ values given by Akagi et al. (2011). The relative uncertainty in $EF_{PM}$ is calculated as the standard deviation divided by the average of $EF_{PM}$ derived from all previous studies of temperate forest $EF_{PM}$ measurements used in GFED (Akagi et al., 2011;
Andreae and Merlet, 2001; van der Werf et al. 2017). The calculated relative uncertainty in GFED $E_{PM}$ is 126% and $E_C$ is 120% (Supplementary Table S1).

2.1.2 FEERv1.0 (Low-Resolution Top-down)

FEER is a global fire emissions inventory that calculates daily average $E_{PM}$ using a traditional top-down approach as

$$E_{PM} = C_e \times FRP$$  \hspace{1cm} (3)

where $C_e$ is an ecosystem-dependent predetermined smoke emission coefficient, and FRP observations are from MODIS. FEER derives $C_e$ using multiple years of coupled MODIS AOD at 550nm and FRP observations and an assumed constant MEE at 550nm of 4.6 m$^2$ g$^{-1}$ derived from previous studies (Reid et al., 2005b). Smoke emission coefficients have been predetermined by FEER and are provided globally at a 1° x 1° resolution (https://feer.gsfc.nasa.gov/projects/emissions/) (Ichoku & Ellison, 2014).

Daily average $E_{PM}$ estimates are provided at a 0.1° x 0.1° resolution through a coupling of FEER smoke emission coefficients and MODIS FRP observations (FEERv1.0-G1.2). For the traditional top-down approach, we calculate daily average $E_{PM}$ estimates for each of the western fires sampled during FIREX-AQ as

$$E_{PM} = \sum \bar{E}_{PM,FEER} \times A_{P,FEER}$$  \hspace{1cm} (4)

where $\bar{E}_{PM,FEER}$ is the area-normalized daily average $E_{PM}$ from each FEER pixel, and $A_{P,FEER}$ is the FEER grid cell area (0.1° x 0.1°). The summation is over all FEER grid cells per fire. FEER grid cells are included if they are within 0.1° of the centroid of the final GeoMAC fire perimeter for each fire. We convert from UTC time to local time following the same approach described in section 2.1.1. We also calculate the average FEER $C_e$ for the fires sampled during the western portion of the FIREX-AQ campaign as the average of all $C_e$ estimates in every 1° grid cell that encompassed at least a fraction of the final GeoMAC perimeter of a fire.

We estimate relative uncertainty in FEER $E_{PM}$ estimates by propagating uncertainty through equation 3. We calculate the relative uncertainty of $C_e$ as the standard deviation divided by the mean of all extracted FEER $C_e$ values used in this analysis, and we obtain the relative uncertainty of MODIS FRP from Freeborn et al. (2014). FEER $C_e$ for Western US wildland fires has a relative uncertainty of 73% and FRP has a relative uncertainty of 27%, yielding a relative uncertainty in FEER $E_{PM}$ of 78% (Supplementary Table S1).

2.2 Emission Rate Estimates from FIREX-AQ

2.2.1 In Situ Measurement Approach (High-Resolution)

We capitalize on the intensive, high spatial and temporal resolution smoke plume measurements from the DC-8 aircraft during FIREX-AQ to calculate $E_C$ and $E_{PM}$ via a novel in situ measurement-driven approach. We assume fire emission rates over time are equal to the flux of smoke as it passes through a vertical slice of the smoke plume, represented as an HSRL.
curtain measured during in situ transects (Figure 1). We calculate $E_C$ and $E_{PM}$ for each wildland fire sampled during FIREX-AQ on a sub-plume (per transect) basis as

$$E_X = \bar{WS} \times \bar{GS} \times \sum_{t_{start}}^{t_{end}} \Delta X_t \times H_t \Delta t$$

where $E_X$ is the emission rate of species $X$ (either carbon or PM), $\bar{WS}$ is the transect average wind speed, $\bar{GS}$ is the transect average ground speed, $\Delta X_t$ is the excess concentration of species $X$ averaged over 10 second intervals to match the horizontal resolution of the HSRL data collected at aircraft measurement time $t$, and $H_t (m)$ is the plume thickness measured by the nadir and zenith pointing HSRL profiles at aircraft measurement time $t$ (Hair et al., 2008). This approach assumes that the vertical distribution of each species is uniform, and the lidar is used to find the vertical extent of the plume. Excess concentrations are calculated by subtracting a background concentration defined as the average concentration 5-10 seconds prior to the start of the transect and 5-10 seconds after the end of the transect. In a few cases, the PM background is elevated during the time interval used to define a background such that the excess mixing ratio is computed as a negative value, and these cases are excluded from the analysis. The time interval from $t_{start}$ to $t_{end}$ is equal to the length of time to complete each transect, and $\Delta t$ is ~10 seconds, which is the horizontal resolution of the HSRL data. $H_t$ is calculated as the sum of HSRL profile bin heights ($\Delta z_t$) where the particle backscatter coefficient ($\beta_t$) is greater than 1 km$^{-1}$ sr$^{-1}$, which was larger than the average background scattering and defined the smoke plume edges for the cases sampled.

$$H_t = \sum_{z=0}^{z=\infty} \Delta z_t [\beta_t > 1 \text{ km}^{-1} \text{ sr}^{-1}]$$

In exceptionally dense smoke plumes, the HSRL laser light was fully attenuated before it could completely pass through the smoke plume edge, and for these cases we assume the smoke plume extended to the surface and neglect the missing portion of the plume above the aircraft. This approach is reasonable as the aircraft tended to sample the smoke plumes near the top of the atmospheric boundary layer, which places a weak upper constraint on the top of the plume just as the surface places a lower constraint on boundary layer mixing processes. An alternative approach to calculate plume thickness using HSRL observations leverages the ratio of the backscatter coefficient in a single HSRL bin to the sum of all backscatter coefficients in a vertical column. We estimate the sensitivity of plume thickness to these two approaches and discover strong agreement (slope = 0.72, $r$ = 0.83), although the alternative approach estimates slightly lower plume thickness on average (Figure S1). We ultimately choose the approach to calculate plume thickness as outlined in equation 6 in an effort to avoid additional uncertainty from relying more heavily on the backscatter coefficient, which may be confounded by changes in aerosol size and/or optical properties rather than mass loading.

Total PM is calculated as the sum of organic aerosol (OA), sulfate, nitrate, ammonium, and black carbon aerosol (BC) reported at standard temperature and pressure conditions and converted to ambient volumetric units. The 50% geometric transmission diameter for the AMS is approximately 600nm, which sufficiently captures the size range for the majority of biomass burning derived particles, with the exception of supermicron ash particles (Adachi et al., 2021; Moore et al., 2021). All components of the submicron non-refractory total PM concentrations are measured using an Aerodyne Time of Flight Aerosol Mass Spectrometer (ToF-AMS) (Canagaratna et al., 2007; DeCarlo et al., 2006; Guo et al., 2021). Refractory BC mass concentrations are provided by a Single Particle Soot Photometer (SP2, Droplet Measurement Technologies). Total carbon is calculated as the sum of CO$_2$, CO, CH$_4$, organic carbonaceous...
aerosol (OC), and BC aerosol. OC is estimated using the OA to OC ratio provided by the ToF-AMS. The CO₂ mixing ratio measurements are obtained using a non-dispersive infrared (IR) spectrometer (LICOR, Inc. Model 7000) adapted for aircraft measurements in a method similar to Vay et al. (2003), while CO and CH₄ mixing ratios are obtained from mid-IR laser absorption spectrometry (Sachse et al., 1991). All three trace gas species were calibrated in-flight with standards from the National Oceanic and Atmospheric Administration Earth Science Research Laboratories (NOAA ESRL) traceable to World Meteorological Organization (WMO) scales. The trace gas measurements were converted from mole fractions to ambient volumetric units by multiplying the mixing ratio by the ratio of the molecular weight to the molecular volume at ambient temperature and pressure conditions.

We estimate relative uncertainty in E_C and E_{PM} using equations 5 and 6. We calculate the following relative uncertainties: WS = 20%, GS = 3%, H₂ = 28%, ΔC = 56%, and ΔPM = 67%. The relative uncertainty for each variable is assumed to be equal to the mean divided by the standard deviation of observations collected during all smoke plume transects. The computed relative uncertainty in E_C is 66% and the relative uncertainty in E_{PM} is 75% (Supplementary Table S1).

2.2.2 Fuel2Fire (High-Resolution Bottom-up)

E_C estimates for all FIREX-AQ wildland fires derived using a bottom-up style approach are publicly available on the FIREX-AQ data archive (https://doi.org/10.5067/SUBORBITAL/FIREXAQ2019/DATA001). This dataset, the Fuel2Fire carbon emissions inventory, is optimized and designed to estimate carbon emissions specifically for the fires sampled during FIREX-AQ. We use Fuel2Fire E_C estimates for the high-resolution bottom-up approach to estimate E_C and E_{PM} on a per transect basis for each of the fires included in this analysis. As a bottom-up inventory, Fuel2Fire calculates E_C in the same way as GFED, following equation 1. The Fuel2Fire emissions inventory derives burned area using a combination of active fire detections from MODIS, VIIRS, and/or Geostationary Operational Environment Satellite Program (GOES-16 and 17 ABI L2 +). Active fire pixels from one or more of these active fire detection products are selected to best match ground-verified interagency situational reports from fire management teams, as well as GeoMAC fire perimeters. Fuel2Fire determines fuel loading using ultra high-resolution (30 meter) fuels data from the Fuels Characteristics and Classification System (FCCS) and models combustion completeness as a function of daily fire weather danger ratings. Total daily carbon emissions are temporally distributed using a diurnal cycle of fire activity derived from geostationary satellite observations of FRP from GOES-16 and 17. Fuel2Fire assumes F_C is 0.5 kg kg⁻¹ (McMeeking et al., 2009; Santín et al., 2015; Yokelson et al., 1997). The archived carbon emissions data has a native temporal resolution that matches GOES-16 and 17 data (5 minutes) and is linearly interpolated to 1 Hz data for consistency with the aircraft data. E_C estimates from Fuel2Fire extend over the course of an entire 24-hour day (local time) that a given fire was sampled during FIREX-AQ.

We convert E_C estimates from the Fuel2Fire inventory to E_{PM} as follows

\[ E_{PM} = \frac{E_C \times EF_{PM}}{F_C} \]  

Here, we obtain E_C from the Fuel2Fire inventory, while E_{PM} is calculated using aircraft observations. We choose to calculate EF_{PM} from in situ observations as opposed to assuming EF_{PM} from a compilation of previous studies in order to investigate the potential influence of the choice in EF_{PM} on differences in emission rate estimates. F_C is assumed to be 0.5 kgC kg-fuel⁻¹,
but we note $F_C$ can vary from 0.35-0.55 (Akagi et al., 2011; Burling et al., 2010; McMeeking et al. 2009; Susott, 1996). We calculate $E_{PM}$ for each in situ smoke plume transect using airborne measurements following the carbon mass balance approach (Ward & Radke, 1993; Yokelson et al., 1996, 1999). Although the smoke age and, thus, probability of plume processing increases as a function of downwind distance from the fire, we assume PM is conserved over the relatively short period of time (0.5-7 hrs) that the smoke has been exposed to atmospheric processing when it was sampled by the DC-8 and attribute any changes in mass concentration to variability in fire activity (Garofalo et al., 2019; Hodshire et al., 2019). The time of emission is not the same as when the DC-8 sampled the plume, so we correct for this time offset by adding smoke age to the time of emission when determining the Fuel2Fire total carbon emission rates on a sub-plume, per transect basis. The smoke age is calculated for each point on the DC-8 transect assuming horizontal straight line advection of the smoke plume at the DC-8 measured wind speed (Wiggins et al., 2020).

We estimate relative uncertainty in $E_C$ and $E_{PM}$ derived from Fuel2Fire by propagating uncertainty through equation 7. The relative uncertainty in $E_C$ is assumed to be 55%, calculated by taking the average divided by the standard deviation of all computed $E_C$ estimates for each fire and every transect included in this analysis. The relative uncertainty in $E_{PM}$ is 39%, computed as the mean of all calculated $E_{PM}$ for all fires divided by the standard deviation. The relative uncertainty in $E_{PM}$ is thus 67% (Supplementary Table S1).

**2.2.3 HSRL-GOES (High-Resolution Top-down)**

We use FIREX-AQ aircraft-based HSRL measurements of aerosol extinction and geostationary satellite observations of FRP from GOES to calculate $E_{PM}$ using a high-resolution top-down approach, referred to as HSRL-GOES. We use the same equation that is used in FEER (Equation 3) to calculate $E_{PM}$ for the western fires sampled during FIREX-AQ on a per transect basis for the high-resolution top-down approach. Instead of using MODIS FRP, we obtain FRP from the GOES-16 and GOES-17 ABI L2 + Fire/hot spot Detection and Characterization product from the Wildfire Automated Biomass Burning Algorithm processing system (Schmidt, 2019). GOES has an exceptionally high temporal resolution (~5-15 mins) with FRP observations that cover the entire continental US at a spatial resolution of 2km (Schmidt, 2019). We time align GOES FRP observations to match the in situ plume sampling time by adding the smoke age to the FRP observation time, and we include all FRP observations within 4km (the spatial resolution of GOES-16 and 17) of a given fire’s final GeoMAC perimeter centroid. FRP per transect is calculated as the sum of all instantaneous FRP observations for a given fire averaged over the in situ plume sampling time for a given transect. The smoke emission coefficient is also calculated for each fire on a per transect basis as follows:

$$C_e = \frac{WS \times GS}{MEE \times FRP_f} \times \sum_{t_{start}}^{t_{end}} \Delta AOT \times \Delta t$$  \hspace{1cm} (8)

where $FRP_f$ is the time-aligned, transect-average GOES FRP, $MEE$ is the transect average MEE calculated from in situ measurements as described below, and $\Delta AOT$ is aerosol optical thickness.
derived from vertically integrating the background-subtracted 532nm HSRL particle extinction coefficient ($\Delta \alpha$) as described by

$$\Delta AOT_t = \int \Delta \alpha \, \Delta z$$  \hspace{1cm} (9)

HSRL is not able to collect measurements immediately above and below the aircraft. We linearly interpolated through the 60m aircraft gap in the HSRL curtains to account for the missing data. Background extinction is defined as the average HSRL extinction profile 10 sec before and after the smoke plume transect. In cases where the laser light fully attenuated before it reached the bottom of the plume, we assume the plume extended to the surface and extrapolate extinction to the ground using the closest measurement to the surface. In limited cases where the beam is completed attenuated in the zenith direction, we integrate over the measured range but do not add any correction as this is expected to be a relatively small contribution as the aircraft was typically flying near the top of the atmospheric boundary layer near plume top. We use the high-resolution inventories (such as FEER) to calculate MEE; however, we note that most top-down in situ measurements from the DC-8 to calculate MEE; however, we note that most top-down inventories (such as FEER) assume a constant MEE of 4.6 m$^2$ g$^{-1}$ derived from previous studies. We calculate transect average MEE as the slope of a reduced major axis regression with a forced zero intercept between total PM and the dry aerosol extinction coefficient at 532nm for each transect. The extinction coefficient is calculated as the sum of dry scattering and absorption coefficients measured by a TSI-3563 Nephelometer at 550nm and a 3-wavelength Particle Soot Absorption Photometer at 532nm (PSAP, Radiance Research) respectively. Scattering coefficients are converted to 532nm to match the absorption coefficients using the angstrom exponent as calculated by the blue and green channels from the nephelometer. Scattering coefficients are corrected for truncation errors following Anderson and Ogren (1998), and PSAP absorption data are corrected following Virkkula et al. (2010). The aerosol extinction humidification factor, $f(RH)$ is assumed to be unity, which is consistent with the FIREX-AQ in-plume measurements.

We estimate the uncertainty in HSRL-GOES $E_{PM}$ by propagating uncertainty through equation 3, where the relative uncertainty in $C_e$ derived following equation 8 is calculated as the mean $C_e$ from all fires divided by the standard deviation (67%), and the relative uncertainty in FRP is assumed to be 40% (Li et al., 2020). The relative uncertainty in HSRL-GOES $E_{PM}$ is thus 77% (Supplementary Table S1).

### 2.3 Comparison of Approaches

We summarize the approaches and relevant equations used in this study to calculate $E_C$ and $E_{PM}$ in Table 1. We evaluate emission rate estimates between the high-resolution bottom-up (Fuel2Fire) and top-down (HSRL-GOES) based approaches against the in situ approach on a per transect basis for individual wildland fires sampled during FIREX-AQ. The relationship between the different approaches is quantified using the slope of a reduced major axis regression with a forced zero intercept, a Pearson’s correlation coefficient, and root mean square error (RMSE). These calculations are performed as a campaign level summary that includes all transects and all fires and for each fire individually.

We compare daily (24 hour local time) average $E_{PM}$ estimates from the three high resolution approaches (In Situ, Fuel2Fire, and HSRL-GOES) to daily average estimates derived
from lower resolution global fire emissions inventories (GFED and FEER). These comparisons are performed on daily average emission rate estimates, as opposed to estimates on a per transect basis, because of the lower temporal resolutions of GFED (3 hr/daily) and FEER (daily).

### 2.4 Smoke Emission Coefficients

The high spatial and temporal resolution of the in situ, bottom-up (Fuel2Fire), and top-down (HSRL-GOES) based approaches provide the opportunity to evaluate smoke emission coefficients that are usually derived using many years of data. Smoke emission coefficients for PM are calculated as the slope of a reduced major axis regression with a forced zero intercept between GOES FRP time aligned to the transect sampling time versus EPM for each of the three high resolution approaches. These computations are also executed as a campaign level summary and for each fire individually. We compare our $C_e$ from the high resolution approaches to the average FEER $C_e$ for the western fires sampled during FIREX-AQ.

### 3 Results and Discussion

#### 3.1 Total Carbon Emission Rates

The derivation of the variables used to calculate $E_C$ using bottom-up approaches are based on assumptions that can lead to both under and overestimation, depending on the data products leveraged by a given fire emissions inventory. We uncover a significant relationship between $E_C$ per transect derived from the high-resolution bottom-up approach (Fuel2Fire) and the in situ approach as shown in Figure 2 (slope = 1.00, $r = 0.82$). However, there is also a non-trivial level of scatter in this relationship (RMSE = 67%), and individual fires considered separately have different correlations and regression slopes.

From Figure 3, we similarly find strong, linear correlations between daily fire average $E_C$ from the in situ measurement based estimates and Fuel2Fire (slope = 1.09, $r = 0.92$, RMSE = 61%) and GFED (slope = 0.20, $r = 0.87$, RMSE = 132%). The daily average $E_C$ estimated using Fuel2Fire are marginally higher than estimates derived from the in situ approach, while the GFED estimates are 80% lower. The strong correlation, but significant offset between GFED and the in situ measurement based approach implies that there may be a systematic bias in one or more of the variables used to calculate the mass of biomass consumed in some traditional bottom-up inventories. In this section, we examine the assumptions and uncertainty in individual variables used to calculate $E_C$ using a bottom-up approach in an effort to understand the differences in $E_C$ estimates derived from Fuel2Fire and GFED relative to the in situ approach.

#### 3.1.1 Carbon Mass Balance

The key assumption in a bottom-up approach is that all burnt carbon is volatilized and released into the atmosphere. This carbon mass balance assumption has recently been scrutinized, because not all fuel that has been thermally altered by a fire is emitted to the atmosphere (Santin et al., 2015; Surawski et al., 2016). Some of the burnt fuel remains on the ground as charred biomass. If the carbon mass balance assumption does not hold, then this could potentially cause an overestimation of carbon emissions derived from bottom-up approaches by up to 50% in temperate forests, depending on levels of combustion completeness (Santin et al., 2015). Our results do not show significant evidence of bias in $E_C$ estimates from Fuel2Fire, but do show a distinct low bias in estimates from GFED. This suggests there are underlying confounding factors to disentangle before it is possible to determine if the assumptions inherent
in the carbon mass balance approach are responsible for a significant bias in bottom-up inventories.

### 3.1.2 Burned Area

The two methods for calculating burned area using a bottom-up approach operate under specific assumptions that could cause either an over or under estimation of carbon emissions. The active fire based method has the potential to overestimate burned area, because it assumes all the area within the resolution of a single active fire detection is burned. Conversely, the burned area based method using MODIS burned area data products (MCD65A1) has been shown to underestimate burned area, because of high omission error in grid cells with smaller proportions of burned area (Boschetti et al., 2019). A recent validation study that compares 500-meter resolution MODIS burned area products (MCD64A1) against 30-meter resolution Landsat data found MODIS underestimated global burned area by 54% (Boschetti et al., 2019). However, MODIS burned area products also have a non-trivial level of uncertainty, approximately 44% (Giglio et al., 2018).

Fuel2Fire, calculates burned area using the active fire approach, while GFED uses MODIS burned area data products. GFED4.1s attempts to address the known small fire driven burned area underestimation from MODIS using a supplementary algorithm known as the small fire boost (Randerson et al., 2012; van der Werf et al., 2017). We compare the GFED and Fuel2Fire burned area estimates in Figure S2, which are in good agreement for the western fires sampled during FIREX-AQ (slope = 0.97, r = 0.93). This indicates that the differences in the two approaches to calculate burned area are not responsible for the low bias we see in GFED emission rate estimates.

### 3.1.3 Combustion Completeness

All state-of-the-art approaches to calculate combustion completeness rely on daily or monthly average observations, and therefore cannot accurately estimate the pronounced sub-daily changes in combustion completeness that occur throughout the diurnal cycle of fire activity. Instead, these methods assume combustion completeness can be estimated using observations averaged over large areas. Combustion completeness in the Fuel2Fire inventory is based on daily fire weather indices, where higher levels of fire danger equate to higher consumption rates, while GFED relies on a biogeochemical model with a monthly time step to estimate combustion completeness.

We expect GFED combustion completeness to be overestimated on days with low fire activity and underestimated on days with high fire activity as a result of the monthly averaging scheme, however that is not the observed trend (Figure 3). Instead, GFED underestimates $E_c$ for almost every fire included in this analysis. It is therefore unlikely that differences in the approaches to calculate combustion completeness strongly contribute to the systematic low bias found in GFED $E_c$ estimates.

### 3.1.4 Fuel Loading

The complexity and variability of fuel type (or land cover) and loading are difficult to accurately represent and validate. Labor intensive high spatial resolution fuel databases, such as the FCCS database used in the Fuel2Fire inventory, are derived from a compilation of previous remote sensing studies, government databases, photos, in situ measurements, and expert opinion (Ottmar et al., 2007). The spatial resolution of FCCS is 30m; however, this resolution is achieved...
through the extrapolation of field-based measurements to ecosystem scales, which relies on a
number of strong assumptions that infer the distribution and composition of fuels from the same,
similarly-aged, spectrally-similar ecosystems are roughly spatially constant. Fuels are constantly
changing in response to seasonal, environmental, and anthropogenic forcing, but the laborious
effort required to develop fuel databases severely restricts the rate at which they can be updated.
As a result, fuel bed databases can remain unchanged and out of date for a number of years
before updates are implemented. This delay can exacerbate the uncertainty and error in fuel
loading estimates. Model based estimates of fuel loading that rely on remote sensing
observations of surface characteristics, like those used in GFED, are similarly challenged by the
limited number of field measurements available to validate estimates. Potential bias stemming
from fuel loading estimates can be negative or positive, depending on the accuracy of initial
estimates and if the database or model correctly implements changes in fuel loading following
ecosystem disturbance mechanisms including fire.

We discover an exceptional uncertainty in GFED fuel loading (111%), however the
uncertainty in the FCCS fuels database used by Fuel2Fire is estimated to be much lower (~70%)
(Keane et al., 2013) (Supplementary Table S1). Combined with the lack of evidence that burned
area or combustion completeness significantly contribute to GFED emission estimate bias, this
implies the differences in fuel loading estimates from the model used in GFED versus the high-
resolution fuels database (FCCS) used in Fuel2Fire is the most likely culprit for the persistent
underestimation of GFED $E_C$ estimates from Western US wildland fires. The agreement we see
in $E_C$ estimates from Fuel2Fire versus the in situ based approach provides confidence for the use
of high resolution fuels databases such as FCCS (Figure 2).

Previous studies aimed at quantifying uncertainty in the parameters used by bottom-up
inventories to calculate emissions have also identified fuel loading as a major source of
uncertainty (French et al., 2004; Urbanski et al., 2011; Prichard et al., 2019). Furthermore, fuel
loading uncertainty likely fluctuates considerably as a function of vegetation type, due to scarce
field validation studies for certain ecosystems and/or mapping errors. Our results highlight the
need for additional field validation studies to constrain fuel loading estimates.

### 3.2 Total PM Emission Rates

We find the strong relationship between Fuel2Fire and the in situ based method persists
for $E_{PM}$ at a sub-plume scale, albeit with a similarly high level of scatter as shown in Figure 4a
(slope = 0.90, $r = 0.77$, RMSE = 61%). We derive $E_{PM}$ from the in situ FIREX-AQ
measurements on a per transect basis in order to minimize the potential influence of emission
factor uncertainty in Fuel2Fire $E_{PM}$ estimates. The high level of spread in the data is likely an
artifact of the uncertainty in $E_C$ from Fuel2Fire caused by the biases and sources of uncertainty
discussed in Section 3.1, most notably the impacts of fuel loading uncertainties. Additionally,
this comparison is based on the assumption that the transport of fire emissions from the ground
to the in-situ transect is accurately modeled in both space and time.

Figure 4b shows a significant relationship between $E_{PM}$ calculated using HSRL-GOES
and the in situ approach at a sub-plume scale (slope = 1.04, $r = 0.82$, RMSE = 48%). While there
is a marginally lower level of scatter in this relationship as shown by the RMSE, HSRL-GOES
slightly overestimates $E_{PM}$ on the lower end of the scale compared to the in situ approach. This
overestimate implies from Equation 3 that either or both the GOES FRP and $C_e$ for these fire
transects are biased high, where it follows from Equation 12 that the latter may be influenced by
a low estimate of the smoke MEE or a high estimate of the optical thickness. A high optical
thickness bias might be due to the extrapolation of HSRL extinction to the surface for cases when the laser light fully attenuates; although, we note the bias is most significant for the lower emission rates, which might discount this hypothesis.

We find strong correlations between daily average $E_{PM}$ estimates from the in situ approach versus estimates from both of the high-resolution approaches, Fuel2Fire (slope = 1.04, $r = 0.93$, RMSE = 39%) and HSRL-GOES (slope = 1.18, $r = 0.89$, RMSE = 47%) (Figure 5). The correlation is weaker and the spread is larger between the in situ based estimates and estimates from the lower-resolution global inventories, GFED and FEER. The systematic low bias seen in GFED daily average $E_C$ estimates is also seen for daily average $E_{PM}$ for all but the smallest fires (slope = 0.21, $r = 0.85$, RMSE = 104%). FEER slightly underestimates $E_{PM}$ from larger fires that emit relatively more PM and overestimates $E_{PM}$ from smaller fires that emit relatively less PM (slope = 1.38, $r = 0.64$, RMSE = 55%). FEER provides no $E_{PM}$ estimates for the Castle fire on both days of sampling, and we exclude these zero estimates from this fire when computing the linear regression and correlation coefficient given their disproportionate weight in skewing the regression.

Global fire emissions inventories are known to significantly differ on $E_{PM}$ estimates from temperate fires, especially in North America (Nikonovas et al., 2017; Pan et al., 2020). In the following sections we use the high resolution airborne in situ measurements of smoke plumes collected during FIREX-AQ to isolate the assumptions and variables responsible for the discrepancy and quantify their relative contributions.

### 3.2.1 Emission Factors

Emission factors are used in bottom-up approaches to convert carbon emissions to emissions of a specific trace gas or particulate species, and emission factor estimates usually come from compilation studies that include in situ measurements from wildland fires and laboratory experiments (Akagi et al., 2011; Andreae, 2019; Andreae & Merlet, 2001; May et al., 2014). The use of such emission factors relies on the assumption that the most representative value can be approximated as the mean of all previous studies. In reality, emission factors are dynamic and vary as a function of combustion completeness, which can fluctuate both spatially and temporally for a given fire. Laboratory studies struggle to represent the complexity of a wildland fire and can disagree with in situ measurements, while in situ measurements are subject to sampling bias (Hodshire et al., 2019; Yokelson et al., 2013). For example, airborne based measurements tend to be limited to daytime sampling of well-developed plumes that have risen to an altitude that is accessible by the aircraft. Consequently, these measurements may be biased towards flaming combustion because nighttime and/or smoldering emissions resulting from less energetic fire activity are not being sampled (Burling et al., 2011; Prichard et al., 2020; Wiggins et al., 2021). The suggested $E_{PM}$ for temperate forests from GFED is 17.6 g kg$^{-1}$, and the mean $E_{PM}$ we calculated using FIREX-AQ in situ airborne measurements is 15.8 ± 4.3 g kg$^{-1}$, which is well within range of the suggested $E_{PM}$ from GFED. Our results suggest $E_{PM}$ does not strongly contribute to bias in bottom-up emission rate estimates from Fuel2Fire or GFED for the fires sampled during FIREX-AQ. However, we acknowledge this analysis focused exclusively on fires with well-developed plumes that were sampled during the daytime, and thus may not be
subject to EF$_{\text{PM}}$ discrepancies that can occur as a result of under sampled smoldering combustion.

### 3.2.2 Smoke Emission Coefficient ($C_e$)

Smoke emission coefficients used by top-down inventories to convert FRP to E$_{\text{PM}}$ are typically derived using multiple years of AOD and FRP observations, but here we use high resolution measurements from FIREX-AQ to calculate $C_e$ over a limited duration for a small number of fires. We find strong to moderate linear relationships between GOES FRP observations and the calculated emission rates from the high resolution in situ approach ($C_e = 5.0$ gPM MW$^{-1}$, $r = 0.75$, RMSE = 165%), Fuel2Fire ($C_e = 8.2$ gPM MW$^{-1}$, $r = 0.94$, RMSE = 46%), and HSRL-GOES ($C_e = 8.4$ gPM MW$^{-1}$, $r = 0.72$, RMSE = 75%) (Figure 6). Individual fires have significantly different $C_e$, and vary depending on which approach was used to calculate E$_{\text{PM}}$ (Table 3), which highlights the sensitivity and natural variability of this parameter. All three of the high resolution approaches estimate a lower $C_e$ for the set of Western US wildland fires included in this study compared to the estimated $C_e$ from FEER (10.6 gPM MW$^{-1}$). However, the calculated $C_e$ are within the large uncertainty (50%) of the $C_e$ for western US fires derived from FEER, and the RMSE is substantial for the in situ approach and HSRL-GOES.

Fuel2Fire temporally distributes emissions using the diurnal cycle of GOES FRP observations, which explains the exceptionally strong linearity and correlation between GOES FRP and E$_{\text{PM}}$ estimates in Figure 6b. HSRL-GOES E$_{\text{PM}}$ estimates shown in Figure 6c continue to have a slight high bias on the lower end of the scale. We find a high bias in E$_{\text{PM}}$ for the Castle fire in all three high resolution approaches compared to what would be expected based on the overall campaign level relationship between FRP and emission rates (Figure 6). The Castle fire had the lowest average excess PM concentrations per transect out of all the fires included in this analysis. The elevated emission rates from all three approaches indicate GOES likely missed some of the FRP, likely due to low temperature smoldering or cloud cover, which is consistent with the low fire severity measured in post-burn satellite data.

FEER uses MODIS FRP observations to calculate $C_e$, but we use GOES FRP. There could be a potential offset between FRP observations between MODIS and GOES as a result of differences in instrument resolution and saturation levels as well as overpass time effects (Li et al., 2019; Xu et al., 2021). The coarse spatial resolution of GOES (2km) limits its capability to detect cool or small fires with low FRP, and could result in an underestimation of FRP by up to 50% globally (Freeborn et al., 2008), which would explain the difference in $C_e$ estimated using the high resolution approaches versus FEER. We use GOES FRP because of the exceptionally high time resolution (5-15 mins) over the continental US versus the twice daily temporal resolution of MODIS or VIIRS. This allows for a more direct comparison between in situ measurements and remote sensing observations. Previous studies have suggested E$_{\text{PM}}$ and thus $C_e$ calculated using MODIS AOD may be systematically biased low, because of a discrepancy between observed AOD from MODIS versus AERONET and MISR (Pan et al., 2020). However, we find agreement between E$_{\text{PM}}$ calculated independently of MODIS AOD and E$_{\text{PM}}$ estimated from FEER, which relies on MODIS AOD observations. The results suggest MODIS AOD observations can be used to
accurately represent atmospheric aerosol mass loading of particulates emitted by Western US wildland fires.

3.2.2.1 Mass Extinction Efficiency (MEE)

The conversion of FRP to PM assumes that variability in particle extinction, and thus AOD, is driven by changes in aerosol mass concentration rather than aerosol intensive properties. Estimates of particle mass extinction efficiency (MEE) are essential to the conversion of AOD to total PM. However, aerosol extinction and other optical properties depend on particle size, morphology, and chemical composition (Seinfeld & Pandis, 2006). The characteristics of biomass burning aerosols are known to vary with fuel type and combustion completeness (McClure et al., 2020; Reid et al., 2005a; Reid et al., 2005b). Furthermore, the physical and optical properties of smoke aerosols rapidly evolve following emission as a result of photochemical aging and aerosol microphysical processes (Akagi et al., 2012; Cappa et al., 2020; Garofalo et al., 2019; Hodshire et al., 2019; May et al., 2014; Shingler et al., 2016). Particle evolution via these processes is additionally influenced by external factors, such as the fire size, rate of dilution, and background aerosol concentrations (Hodshire et al., 2019). The assumption that variability in AOD is entirely due to changes in particle concentration oversimplifies the complex interactions of smoke particle microphysical processes and photochemical aging. Some top-down inventories attempt to reconcile this discrepancy by calculating a separate $C_e$ for each individual ecosystem. However, this is likely not sufficient to fully address the variability in smoke aerosol extinction that often occurs even in smoke plumes from fires within a single ecosystem type.

Top-down inventories, including FEER, usually assume a constant MEE of 4.6 m$^2$ g$^{-1}$ based on a compilation of previous studies (Ichoku & Kaufman, 2005; Reid et al., 2005b). The compilation found MEE varied between 3.4 – 5.1 m$^2$ g$^{-1}$ for biomass burning particles of all ages across a diverse set of ecosystems (Figure S3) (Reid et al., 2005b). We find MEE values vary between 2 - 6 m$^2$ g$^{-1}$ for the FIREX-AQ smoke plumes and that the MEE increases asymptotically as a function of smoke age (Figure 7). Our observations indicate MEE approaches the mean from previous studies as the smoke rapidly evolves in the early hours after emission. The rate at which MEE increases with smoke age is variable among the fires included in this analysis and does not appear to depend on the plume PM concentration. Our range of MEEs for smoke plumes from Western US wildland fires using high-resolution in situ measurements is larger than what has been observed in previous studies. Our results emphasize the variability that can occur in smoke MEE, and suggest that the top-down approach is likely more sensitive to MEE than previous studies imply. The use of a constant MEE could lead to a high bias for fires with lower excess PM concentrations and a low bias for fires with higher excess PM concentrations, which would explain the trend we see in Figure 5 where FEER underestimates fire $E_{PM}$ from the most actively burning fires and overestimates $E_{PM}$ from smaller, weaker fires.

3.2.2.2 Instantaneous Observations of FRP and AOD

FEER uses daytime MODIS FRP and AOD observations to derive $C_e$ and assumes that the FRP at the time of observation is directly related to the smoke plume AOD. However, fires have a clear, ecosystem dependent diurnal cycle with the time of peak fire activity depending on the specific landcover, geographic location, elevation, slope, aspect, and type of fire (e.g., wildland, prescribed, crown, surface). FRP observations represent the instantaneous fuel consumption and corresponding emissions of a given fire, but AOD observations represent the
total mass of aerosols emitted by a fire, including the time period when the fire was active before the satellite overpass time. The variability in FRP that occurs over the course of a day has a clear impact on the total mass of smoke particles in the plume as a function of downwind distance from the fire and wind speed, but polar orbiters, like MODIS do not have the temporal resolution to quantify this relationship. As a result, \( C_e \) derived using FRP and AOD observed after the peak in diurnal fire activity are likely overestimated, while \( C_e \) derived using FRP and AOD observed prior to the peak may be slightly underestimated. The exact nature and magnitude of the potential bias would depend on a specific fire’s diurnal cycle and the age of the smoke captured in the satellite observations of AOD. With respect to the calculation of \( E_{PM} \) using a predetermined \( C_e \), the time offset between MODIS overpass times and peak diurnal fire activity could similarly cause a bias. \( E_{PM} \) could potentially be biased high or low if the satellite overpass time occurred either before or after the peak in diurnal fire activity, and if the observed FRP was higher or lower than the daily average FRP.

A recent study by Mota and Wooster (2018) demonstrated fire emission rates can be calculated at a high temporal and spatial resolution (hourly and 0.05° x 0.05°, respectively) using a top-down approach that relies on geostationary satellite observations of FRP from the Spinning Enhanced Visible and InfraRed Imager (SEVIRI) to avoid bias caused by inadequate sampling of a fire’s diurnal cycle. We compare geostationary satellite observations of FRP from GOES that match the overpass times of MODIS with the average of all FRP observations over the course of a day for each fire to investigate potential bias in \( E_{PM} \) estimates from FEER. The Western US wildland fires sampled during FIREX-AQ exhibited peak fire activity from 3-6 pm local time (Pacific daylight time, UTC-7) (Wiggins et al., 2020). Meanwhile, local MODIS overpass times are ~10:30am for the Terra satellite and ~1:20pm for Aqua. We find average GOES FRP at the time of the MODIS overpasses is double the daily average FRP from GOES (Figure S4), which could be partially responsible for the overestimation in FEER \( E_{PM} \) estimates for smaller fires that we see in Figure 5.

**4 Summary and Conclusions**

We present a comprehensive evaluation of total carbon and aerosol emission rate estimates computed using the methodologies and assumptions that are commonly employed by global inventories used by models. These emissions inventories have the monumental task of capturing the composition, magnitude, and temporal variability of fire emissions from nearly every ecosystem on Earth. They are critical for the representation of wildland fires in large scale models, and only recently have sufficiently comprehensive observational datasets become available to evaluate their performance. One such study is the joint NASA/NOAA FIREX-AQ airborne mission that took place in 2019. Here, we extend the methods and assumptions employed by emissions inventories to develop state-of-the-art, high-resolution emission rate estimates for each of the western FIREX-AQ fires, which are based on detailed information garnered from ground, airborne, and satellite assets.

We discover excellent agreement between the high-resolution emission rate estimates calculated using integrated airborne in situ and lidar observations and the high-resolution top-down (HSRL-GOES) and bottom-up (Fuel2Fire) estimates at unusually high sub-plume spatiotemporal resolution. While there is considerable scatter in the one-to-one plots comparing Fuel2Fire to the airborne in situ data, the emissions rate estimates for both total carbon and PM are not consistently biased between these methodological approaches. HSRL-GOES appears to slightly overestimate \( E_{PM} \) toward the lower end of the observed range of variability (which
appears to also scale with FRP). Emission rate estimates calculated using the lower resolution
global fire emissions inventories, FEER and GFED, have a weaker relationship with the high-
resolution approaches and show evidence of systematic bias, which is most apparent for GFED.

We discuss, in detail, the key assumptions employed by bottom-up approaches and
conclude that the strong performance of the Fuel2Fire inventory stems from detailed information
about fuel type and loading that are parameterized with significant uncertainty in the global
inventories. In addition, we note that the high-temporal resolution of the Fuel2Fire dataset also
allows it to capture the entire diurnal cycle of the fire activity, which also serves to improve its
predictive skill. This hints that the high temporal resolution of geostationary satellite
observations of FRP could be used to correct the bias caused by satellite overpass times. With
respect to top-down approaches, we find a larger range in MEE for this small subset of Western
US fires than what has been reported in a compilation of previous studies that includes MEE
from fires in a diverse selection of global ecosystems. The high resolution top-down approach
(HSRL-GOES) allowed for the application of variable MEE obtained from sub-plume in situ
measurements. HSRL extinction measurements of the smoke plumes sampled during FIREX-AQ
combined with geostationary satellite observations of FRP offered an exceptionally detailed
measure of AOD and FRP associated with the smoke plume. The use of a constant MEE to
convert AOD to PM in top-down approaches combined with bias from assumptions related to
instantaneous observations of FRP and AOD are likely responsible for the underestimation in
FEER $E_{PM}$ for larger fires and overestimation for smaller fires.

Finally, it’s important to note that it is not yet computationally practical or feasible for
global fire emissions inventories to achieve the level of complexity and detail in the high-
resolution approaches presented here. We use these approaches to investigate discrepancies
between top-down and bottom-up $E_{PM}$ estimates for Western US wildland fires. However, this
collection of fires represents only a small subset of the total number of fires that burn every year
in the Western US and may not be a perfect representation of the complexity that can exist in fire
emissions. In short, we have the luxury of evaluating the skill of the global emissions inventories
for a small subset of wildland fires for which we have unprecedentedly comprehensive data, but
we would be wise to remember that the goal of global emissions inventories is to represent all
fires reasonably well rather than to represent a few fires perfectly. Consequently, it may be
premature to adopt new values for, e.g., the smoke emission coefficient based solely on the
FIREX-AQ dataset. Our analysis does emphasize areas of large uncertainty, however, that may
be improved. One is the estimate of fuel type and loading that likely contributes to the scatter we
see in the bottom-up emission rate estimates from GFED and Fuel2Fire. Burned area and aerosol
mass emission factors do not appear to be large sources of uncertainty as there is good agreement
seen for both GFED and Fuel2Fire for both of these metrics. The importance of the high-
temporal resolution observations of both FRP and smoke AOD afforded by the geostationary
satellites currently in orbit cannot be overstated, as a lack of complete orbital coverage is also
likely to be a strong contributor to the inventory emissions underestimates. The use of a constant
MEE to convert AOD to PM should be revisited in light of the much higher variability we find in
MEE observations for such a limited number of fires, which accentuates the need for additional
measurements of this key variable. In summary, both top-down and bottom-up global fire
emissions inventories suffer from assumptions that may hold true in the aggregate, but break
down on an individual fire basis. The strong agreement that we show here between the high-
resolution approaches holds promise for future fire emissions inventories as advances in remote
sensing, improved computational efficiency, and a more complete understanding of fire behavior begin to offer opportunities to increase the accuracy and resolution of global fire inventories.

Appendix: List of Variables and Common Units

Note: units are included here only as examples and do not consider any unit conversions that may be necessary for the equations given in the text.

| Variable | Description | Unit |
|----------|-------------|------|
| $\alpha_t$ | HSRL extinction coefficient | km$^{-1}$ |
| $A_{P,FEER}$ | FEER pixel area | km$^2$ |
| $A_{P,GFED}$ | GFED pixel area | km$^2$ |
| AOD | Aerosol optical depth | unitless |
| $\beta$ | HSRL backscatter ratio | km$^{-1}$ sr$^{-1}$ |
| BA | Burned area | m$^2$ |
| CC | Combustion completeness | % |
| $C_e$ | Smoke emission coefficient | gPM MW$^{-1}$ |
| $\Delta C$ | Excess mass concentration of C | $\mu$gC m$^{-3}$ |
| $\Delta PM$ | Excess mass concentration of PM | $\mu$gPM m$^{-3}$ |
| $\Delta t$ | HSRL curtain pixel width | s |
| $\Delta z$ | HSRL curtain pixel height | m |
| $E_C$ | Emission rate of total carbon | kgC s$^{-1}$ |
| $\hat{E}_C$ | Area-normalized emission rate of total carbon | kgC m$^2$ s$^{-1}$ |
| $E_{PM}$ | Emission rate of total PM | kgPM s$^{-1}$ |
| $\hat{E}_{PM}$ | Area-normalized emission rate of total PM | kgPM m$^2$ s$^{-1}$ |
| $F_{PM}$ | Particle mass emissions factor | gPM kg biomass consumed$^{-1}$ |
| $F_C$ | Mass fraction of carbon in the fuel | gC kg biomass consumed$^{-1}$ |
| FL | Fuel loading | g biomass m$^2$ |
| FRP | Fire radiative power | MW |
| H | Plume vertical thickness | m |
| MEE | Particle mass extinction efficiency | m$^2$ g$^{-1}$ |
| $\overline{MEE}$ | Aircraft transect-average MEE | m$^2$ g$^{-1}$ |
| PM | Particle mass concentration | $\mu$gPM m$^{-3}$ |
| $\overline{GS}$ | Transect-average DC-8 aircraft ground speed | m s$^{-1}$ |
| $\overline{WS}$ | Aircraft transect-average wind speed | m s$^{-1}$ |

Acknowledgments, Samples, and Data

We thank Barry Lefer and the NASA Tropospheric Chemistry Program and NOAA for funding support. EBW was supported by a NASA Postdoctoral Fellowship. We thank the pilots and crew of the NASA DC-8 aircraft. We thank Tim Marvel for producing Figure 1. All FIREX-AQ data are publicly available online at: https://doi.org/10.5067/SUBORBITAL/FIREXAQ2019/DATA001 MS, HG, PCJ and JLJ acknowledge support by NASA grants 80NSSC18K0630 and 80NSSC19K0124. CI acknowledges partial support from NOAA Educational Partnership Program for Minority Serving Institutions (NOAA/EPP/MSI) under agreement no. NA16SEC4810006. CES was supported in part by the NOAA cooperative agreement with CIRES, NA17OAR4320101.

Conflict of Interest
The authors declare no conflicts of interest or competing interests.

Figure 1. Conceptual image of a typical wildland fire and smoke plume observed during FIREX-AQ as well as the observational platforms and analysis approaches. The DC-8 flight track is given in red and colored by in situ particle concentrations for the cross-sectional legs. As described in the text, the DC-8 initially completes a longitudinal run where the nadir HSRL measurement provides the full smoke curtain below the aircraft, which is then followed by a series of successively downwind flight legs where the nadir- and zenith-pointing HSRL curtains are used to contextualize the cross-sectional, in situ measurements. Image credit: NASA / Tim Marvel.
**Figure 2.** Relationship between total carbon emission rates ($E_C$) from the high resolution bottom-up approach, Fuel2Fire, and the in situ approach. Different markers correspond to specific fires and repeated markers correspond to different transects of the same fire. The green line shows the fit between $E_C$ using a reduced major axis regression with a forced zero intercept. The dashed black line shows a perfect 1:1 relationship for reference. The slope for the linear fit, Pearson’s correlation coefficient ($r$), and root mean square error (RMSE) is given in the legend.
Figure 3. Relationship between daily fire average total carbon emission rates ($E_C$) from Fuel2Fire and GFED versus the in situ measurement based approach. Different markers correspond to specific fires. The green line shows the fit between Fuel2Fire $E_C$ estimates versus the in situ approach using a reduced major axis regression with a forced zero intercept. The yellow line shows the fit between GFED $E_C$ estimates versus the in situ approach. The dashed black line shows a perfect 1:1 relationship for reference. The slope for the linear fit, Pearson’s correlation coefficient (r), and root mean square error (RMSE) is given in the legend.
Figure 4. Relationship between total PM emission rates (E_{PM}) derived from the high-resolution bottom-up approach (Fuel2Fire) versus in situ shown in panel a, and the same relationship between the high resolution top-down aircraft approach (HSRL-GOES) and the in situ approach shown in panel b. The green line shows the reduced major axis regression with a forced zero intercept for Fuel2Fire E_{PM} estimates versus in situ, and the blue line shows the fit for the HSRL-GOES E_{PM} estimates versus in situ. Legend gives the slope for the linear fit, Pearson’s correlation coefficient (r), and root mean square error (RMSE).
Figure 5. Daily fire average PM emission rates ($E_{PM}$) from Fuel2Fire, HSRL-GOES, GFED, and FEER compared to estimates from the in situ approach. Green markers represent estimates from Fuel2Fire and the green line represents the reduced major axis regression with a forced zero intercept between Fuel2Fire estimates and in situ estimates. Blue markers and line represent HSRL-GOES estimates and regression. Purple markers and line represent FEER estimates and regression. Orange markers and line represent GFED estimates and regression. The slope for the linear fit, Pearson’s correlation coefficient ($r$), and root mean square error (RMSE) is given in the legend.
Figure 6. Relationship between GOES FRP and total PM emission rates ($E_{PM}$) derived from the in situ approach (panel a) and the same relationship for Fuel2Fire (panel b) and HSRL-GOES (panel c). The red line shows the fit to a reduced major axis regression with a forced zero intercept for the GOES FRP versus in situ comparison, the green line shows the fit for Fuel2Fire, and the blue line shows the fit for HSRL-GOES. The slope of each regression is equal to the smoke emission coefficient ($C_s$). The dashed grey line is the $C_s$ derived from FEER and the grey shading represents the corresponding uncertainty range. Legend gives the slope for the linear fit, correlation coefficient (r), and root mean square error (RMSE %).
Figure 7. Mass extinction efficiency (MEE) versus smoke age per transect for each fire. Markers are colored as a function of transect mean excess PM concentration. The constant MEE assumed by FEER is shown as the dashed black line for reference.

**Table 3.** Reduced major axis regression slope (m), Pearson’s correlation coefficient (r), and root mean square error (RMSE) for GOES FRP versus total PM emission rates (E_{PM}) for the in situ approach, Fuel2Fire, and HSRL-GOES per individual fire. The slope is equal to the smoke emission coefficient (C_{e}).
Reconciling Assumptions in Bottom-up and Top-down Approaches for Estimating Aerosol Emission Rates from Wildland Fires using Observations from FIREX-AQ

Figures S1 to S4
Table S1
Figure S1. Relationship between two different methods to calculate plume thickness per transect for each fire. X-axis shows plume thickness calculated using equation 6 and y-axis shows plume thickness calculated as a function of the backscatter coefficient distribution throughout the HSRL curtain. Blue line shows the fit to a reduced major axis regression with a forced zero intercept. Pearson’s correlation coefficient (r) and root mean square error (RMSE) are given in the legend.
Figure S2. Total daily burned area per fire from Fuel2Fire versus GFED4.1s. The brown line shows the fit to a reduced major axis regression with a forced zero intercept. The slope and correlation coefficient are given in the legend. The black dashed line shows a perfect 1:1 relationship for reference.
Figure S3. Mass extinction efficiency (MEE) calculated using in situ aircraft measurements for each fire per transect versus smoke age. Colored lines represent ecosystem average mass extinction efficiency for biomass burning particles taken from Reid et al. (2005b). Solid lines show MEE from fresh smoke (less than one day old) and dashed lines show MEE calculated using aged smoke (older than one day). The assumed MEE used by FEER is shown as the black dashed line.
Figure S4. Daily average GOES FRP observations per fire versus average GOES FRP observations within 30 mins of the overpass times for MODIS onboard both Aqua and Terra per fire. The teal line shows reduced major axis regression line with the slope and correlation coefficient given in the legend. The black dashed line shows a perfect 1:1 relationship for reference.
Table S1. Relative uncertainty (δ) given as a percentage for \( E_{PM} \) and \( E_C \) (when available) derived using GFED, FEER, in situ measurements, Fuel2Fire, and HSRL-GOES. From left to right the dependent variables are broken down into the individual independent variables required for their calculation. Relative uncertainty for each independent variable is calculated as the standard deviation (σ) divided by the mean (µ), and relative uncertainty for each dependent variable is computed by error propagation through the equation by which they are defined. If the mean and standard deviation are not available, the relative uncertainty for a variable is taken directly from the corresponding reference. Mean, standard deviation, and interquartile range (IQR) are derived from aircraft observations during smoke plume transects and averaged over all the Western US wildland fires included in this study or calculated based on data from previous studies when available.
