IS THE CORE OF M87 THE SOURCE OF ITS TeV EMISSION? IMPLICATIONS FOR UNIFIED SCHEMES

ABSTRACT

M87 has recently been shown to be a TeV source that is likely to be variable. Based on this and on contemporaneous optical and X-ray monitoring, we argue that the source of the TeV emission is the core of M87 and not one of two jet knots (HST-1 and A), with an X-ray brightness comparable to that of the core. We model the TeV emission in the core as inverse Compton (IC) emission from the base of the jet. Homogeneous models fail to reproduce the spectral energy distribution (SED) and, in particular, the TeV flux. They also fail to comply with the unified scheme of BL Lacertae (BL) objects and FR I radio galaxies. A jet that decelerates from a Lorentz factor \( \Gamma \approx 20 \) down to \( \Gamma \approx 5 \) over a length of \( \sim 0.1 \) pc reproduces the observed SED of the M87 core and, when aligned with the line of sight, produces a SED similar to those of TeV BLs. The TeV flux in the decelerating jet model is successfully reproduced as upstream Compton (UC) scattering, a recently identified emission mechanism, in which energetic electrons of the upstream faster flow upscatter the low-energy photons produced in the slower downstream part of the flow.

Subject headings: galaxies: active — quasars: general — quasars: individual (M87) — radiation mechanisms: nonthermal — X-rays: galaxies

1. INTRODUCTION

Gamma-ray emission in GeV energies has been detected in several bright BLs (Hartman et al. 1999). A handful of nearby, bright BLs have been also detected in the TeV regime (e.g., Aharonian et al. 2005). Gamma-ray emission at some level is expected from radio galaxies, since according to the unified scheme (e.g., Urry & Padovani 1995), BLs are FR I radio galaxies (Fanaroff & Riley 1974), with their relativistic jets oriented toward the observer. So far, the only radio galaxies detected in gamma-rays are the FR I galaxies Cen A (Sreekumar et al. 1999) and M87 (HEGRA, Aharonian et al. 2003; HESS, Beilicke et al. 2004) at TeV energies. Also, a tentative GeV detection of NGC 6251 (Mukherjee et al. 2002) was strengthened by its hard X-ray detection (Foschini et al. 2005). M87 is among the nearest galaxies with a bright radio/optical/X-ray jet. Due to its proximity (a distance of 16 Mpc), the jet has been studied with unparalleled spatial resolution (e.g., Perlman et al. 1999, 2001 and references therein). The synchrotron emission extends to X-ray energies in all jet knots, as well as in the core (e.g., Perlman et al. 2001; Marshall et al. 2002; Wilson & Yang 2002; Perlman & Wilson 2005). Hubble Space Telescope (HST) observations of the core (Tsvetanov et al. 1998) showed variability on timescales of \( \sim 1 \) month. HST and Chandra semimonthly monitoring of the jet during the last 3 years (Harris et al. 2003, 2005; Perlman et al. 2003) established the broadband nature of this variability. Surprisingly, these observations detected an enormous (a factor of \( \sim 50 \)) on-going flare in the jet component HST-1, 0′8 (60 pc projected) from the core, with similar variability timescales.

The discovery of flaring optical and X-ray emission established an important link between M87 and the BLs, as did the detection of apparent superluminal motion in the jet at radio (Biretta et al. 1995) and optical (Biretta et al. 1999) frequencies. The apparent superluminal velocities in the optical of \( \nu _{\text{app}} \approx 6c \) require a jet orientation angle \( \theta \approx 19^\circ \) and \( \Gamma \gtrsim 6 \). The detection of TeV emission constitutes another link between FR I galaxies and BLs. The TeV data appear to indicate significant variability, as the 1998/1999 (HEGRA) and 2003/2004 (HESS) fluxes differ by over a factor of 3 at \( \gtrsim 3 \) \( \sigma \) significance (Beilicke et al. 2004). In BLs, correlated X-ray and TeV variations (e.g., Takahashi et al. 1996) suggest that the TeV emission is produced at the core. In the case of M87, it is necessary to consider as possible TeV emitters three components with comparable optical and X-ray synchrotron luminosity: the core, HST-1, and knot A, an extended jet feature located 12′ from the core.

Based on the likely TeV variability, we argue in § 2 that the most plausible source of the TeV emission is the core and not HST-1 or knot A. In § 3 we consider the modeling constraints imposed by the core SED and the unified scheme and show that homogeneous models cannot satisfy these constraints. We then show (§ 3.1) that a decelerating relativistic jet can solve these problems. Finally, in § 4 we sum up our conclusions.

2. THE SOURCE OF THE TeV EMISSION: VARIABILITY CONSTRAINTS

The production of TeV photons requires TeV energy electrons, which also emit optical/X-ray synchrotron radiation, resulting in correlated TeV and optical/X-ray variability. The possible TeV emission sites are, therefore, the brightest optical/X-ray features of the M87 jet. These are the core and knots A and HST-1, all of comparable optical and X-ray fluxes (within a factor of \( \sim 5 \)–10). We now use the fact that the TeV emission has likely dropped by a factor of \( \sim 3 \) between 1998/1999 and 2003/2004 to constrain the actual TeV source.

We first consider knot A, one of the largest bright regions in the M87 jet, with its flux maximum region \( \sim 1'' \times 0.7'' \) in HST (Sparks et al. 1996) and Chandra (Perlman & Wilson 2005) images, translating to 80 pc \( \times 55 \) pc (projected). Such a large region cannot vary on timescales of a few years, and indeed, monitoring by both the Röntgensatellit (ROSAT; Harris et al. 1999) and Chandra (Harris et al. 2005) does not detect variability of more than \( \sim 10\%–20\% \) in the X-rays.

We turn now to knot HST-1, which is currently exceeding the core flux in the optical, UV, and X-rays by factors of \( \gtrsim 2 \)–5.
depending on the band (Harris et al. 2003, 2005; Perlman et al. 2003). In the spring of 2004, the X-ray flux of HST-1 was \( \sim 3 \) times brighter than it was in the spring of 2003, and since 1998/1999 the increase has been far larger, nearly a factor of 50. By comparison, there is no evidence of an increase in TeV flux from 2003 to 2004 or from 1998 to 2004 (Aharonian et al. 2003; Beilicke et al. 2004). Since the X-ray and TeV variations are not correlated, the contribution of HST-1 to the TeV output of M87 seems not to be significant. This may indicate a low synchrotron photon compactness for HST-1, which can be used to set, in a manner similar to that of Stawartz et al. (2004) for knot A, a lower limit on its magnetic field.

Having excluded knots A and HST-1, we turn to the core. HST, ROSAT, and Chandra monitoring (Harris et al. 1999, 2003; Perlman et al. 2003; D. E. Harris 2005, private communication) suggest that its variations may be similar to those observed by HEGRA and HESS in 1998/1999, and 2003/2004. We therefore believe that the most likely source for the TeV emission is the core of M87.

3. MODELING THE CORE SPECTRAL ENERGY DISTRIBUTION

Given the \( \sim 1 \) month variability timescale of the core emission, its modeling requires contemporaneous broadband observations. The most complete coverage of the core SED is that of 2003 April and May (Fig. 1). We include noncontemporaneous radio and IR data (plus signs), given that the amplitude of the core variability does not exceed a factor of \( \sim 2 \) amplitude. We also plot the 2 \( \sigma \) EGRET upper limit (Sreekumar et al. 1996), with the gray band reaching up to a flux 4 times larger than the detection limit, as expected when the IC seed photons are the source’s synchrotron photons: a change in the electron injection results respectively in linear and quadratic changes of the synchrotron and IC fluxes.

The synchrotron peak between \( 10^{12} \) and \( 10^{14} \) Hz corresponds to a cooling break rather that to a cutoff of the electron energy distribution (EED), because this component exhibits a power-law shape that extends to X-ray energies (e.g., Marshall et al. 2002). This can be seen in the 2003 spectral data (Perlman et al. 2003; Harris et al. 2003). The decrease in the synchrotron SED from 2003 April to May must be accompanied by a quadratic decrease in the IC SED. If there was no synchrotron contribution in the X-rays, the X-ray spectral slope should have remained constant, with only a reduction of the X-ray flux. However, the X-ray slope steepens, suggesting a significant synchrotron contribution in the low state. Note that an extrapolation of the two higher energy fluxes (1.4 and 4.0 keV) down to 0.5 keV overproduces the 0.5 keV flux in both 2003 April and May. This may be due to an intrinsic absorption component (Perlman & Wilson 2005).

The SED of the core of M87, together with the FR I–BL unification (Urry & Padovani 1995), argues against a homogeneous model for the core. The synchrotron SED of TeV BLs is characterized by a spectral break at \( \sim 10^{17}–10^{18} \) Hz, with the SED still increasing above this break, reaching its peak at \( \sim 10^{19}–10^{20} \) Hz, beyond which it exhibits a cutoff (e.g., the 1997 flare of Mrk 501; Krawczynski et al. 2000). This is in strong contrast with the declining IR/optical/X-ray SED of the core of M87. Because relativistic motion preserves the SED shape, simply shifting it along the frequency and luminosity axes, a simple boosting cannot shift the SED of the core of M87 into the mold of the SED of the TeV BLs.

Even if M87 is a special case that, if aligned, does not resemble the TeV BL Lacs, we still need to reproduce its SED.

This turns out to be practically impossible for the homogeneous model. To sketch why this is the case, we will make use of four quantities derived or constrained by observations: the synchrotron peak frequency \( \nu_s = 10^{12}–10^{14} \) Hz, the synchrotron peak luminosity \( L_p \approx 10^{41} \) erg s\(^{-1}\), the Compton dominance (ratio of IC to synchrotron luminosity) \( C_d \approx 1 \) to a few, and the variability timescale \( t_{var} \approx 1 \) month. The bolometric synchrotron luminosity is \( L_{p,\text{bol}} \approx L_p k_\nu \), where \( k_\nu \approx 2/(3 - p) \) and \( p \) is the index of the injected power-law electron distribution. If \( \gamma_0 \) is the Lorentz factor where the cooling time equals the escape time, \( \gamma_0 \approx B^{-2}R^{-1} \), where \( B \) is the magnetic field and \( R \) is the radius of the source, and \( \nu_c \approx B\gamma_0^3 \approx dB\gamma_0^{-3} \), the usual Doppler factor. Noting that \( C_d = U_1/U_\nu \), where \( U_\nu \approx L_{p,\text{bol}}R^{-3/2}d^{-3} \) is the synchrotron photon energy density and \( U_\nu = B^2/(8\pi) \) is the magnetic field energy density, we have \( C_d \approx L_p k_\nu R^{-2}B^{-3}d^{-4} \). Using these expressions for \( \nu_s \) and \( C_d \) together with \( R \sim ct_{var} \), we obtain \( B \approx \delta^3 C_d k_\nu^{-1}L_p^{-1}k_\nu^{-1} \) and \( \delta \approx \nu_s L_p^{2/3}k_\nu^{1/3}C_d^{1/3}t_{var}^{-1} \). The last expression permits only a very narrow range \( \delta \approx 1–2 \), even after allowing for a generous range in the SED-derived parameters. Using the above and noting that the peak of the synchrotron self-Compton (SSC) component is at a frequency \( \nu_{SSC} \approx \nu_s/\gamma_0^2 \), we obtain

\[
\nu_{SSC} \approx 1.4 \times 10^{23} \delta^2 \nu_s^{14} t_{var, m} \left( \frac{C_d}{L_p k_\nu} \right)^{1/2} \text{Hz,}
\]

where \( \nu_{s,14} = \nu_s/10^{14} \), \( L_{p,41} = L_p/10^{41} \), and \( t_{var, m} \) is the variability timescale in months. For a SED-derived set of parameters \( (L_{p,41} = 1, C_d = 1, k_\nu = 8.33) \) for \( p = 2.6 \) required by spectral fitting, the SSC component cannot peak at \( \nu_{SSC} \approx 10^{23} \) Hz, even for \( \nu_s = 10^{14} \) Hz.

While at \( \nu_{SSC} \) the emission is in the Thomson regime, due to the reduced Klein-Nishina cross section the SSC luminosity...
Decelerating Flow and Upstream Compton Scattering

It has been noted (Georganopoulos & Kazanas 2003b, hereafter GK03b) that homogeneous models can fit the SED of TeV BLs only by invoking very high Doppler factors ($\delta \sim 50$; e.g., Krawczynski et al. 2002). Similarly fast flows (Perlman et al. 2003) are required by homogeneous models if one wants to relate the M87 variability timescale ($\sim$1 month) with those of TeV blazars (about a few hours). These values are in strong disagreement with the BL–FR I unification because they severely underpredict the observed FR I luminosities and overpredict their number counts (Chiaberge et al. 2000; Trussoni et al. 2003). They also conflict with the slow apparent motions ($u_{app} \approx c$) in the parsec-scale jets of TeV BLs (Marscher 1999; Piner & Edwards 2004, 2005). This motivated GK03b to propose that TeV BL jets decelerate at subparsec scales from an initial Lorentz factor $\Gamma_0 \sim 10$–20 down to $\Gamma \sim$ a few. In such flows, electrons are more energetic in the faster base of the flow and are radiatively cooled to lower energies as they advect downstream, where the jet decelerates. Beaming, hence, is frequency dependent. In addition to this, upstream Compton (UC) scattering, a newly identified mechanism (Georganopoulos & Kazanas 2003a) in which the energetic electrons of the upstream fast flow “see” the seed photon field produced by the lower energy electrons of the slower downstream flow boosted, increases the level and beaming of high-energy Compton emission.

We apply this model to the core of M87, assuming a deceleration from $\Gamma_0 = 20$ to $\Gamma = 5$ over a distance of $3 \times 10^{17}$ cm. We plot the SED as seen at an angle $\theta = 13^\circ$ for two different jet luminosities in Figure 2. In both cases most of the observed power comes from the slower part of the flow (dotted lines), although the TeV flux is UC emission from the fast base of the flow (dashed lines). Note that as in homogeneous models, a decrease of the jet luminosity (bottom panel) results in a steeper (when lower) X-ray SED, in agreement with observations.

To check whether, in addition to reproducing the SED, this model can reproduce the qualitative characteristics of TeV BLs, we plot in Figure 3 in thick lines the same SED viewed at $\theta = 1/10$ for comparison we replot in thin lines the SED viewed at $\theta = 13^\circ$. While at $\theta = 13^\circ$, $v_{\gamma} \sim 10^{12.5}$ Hz corresponds to the EED cooling break, at $\theta = 29^\circ$ the increased beaming in the fast base of the flow dominates the high-energy emission, resulting in $v_{\gamma} \sim 10^{17}$ Hz. The IC flux increases more than the synchrotron, due mostly to UC emission from the fast base of the flow, resulting in a Compton dominance $C_\gamma \approx 20$, comparable to that of 1ES 1426+428, the most Compton-dominated TeV BL (Costamante et al. 2003).

4. Discussion

The 1998/1999 TeV flux of M87 is higher than the 2003/2004 flux by over a factor 3 at $\sim 3 \sigma$ significance (Beilicke et al. 2004). Based on this and on optical and X-ray variability constraints, we argue that the source of the TeV emission of M87 is its core, as has been previously predicted both in the context of leptonic (Bai & Lee 2001) and hadronic models (Protheroe et al. 2003). We exclude knot A because of its large

$E_{\gamma} \sim 1/20$ (M. Georganopoulos et al. 2005, in preparation), than anticipated in the Thomson case, $E_{\gamma} \sim 1/20$. Because of this steeper SED at the upper end of the SSC component and the upper limit on $\nu_{SSC}$ (see eq. [1]), homogeneous models fail to match the observed TeV flux. A typical example of this is shown in Figure 1, where we plot the SED for two different jet powers. Note how in the low state the stronger reduction in the line is shown in Figure 1, where we plot the SED for two different jet luminosities. The solid lines represent the synchrotron and Compton luminosity of the fastest fifth of the flow, while the dotted lines represent that of the rest of it. Bottom: Same, but with reduced jet power, $L_{\gamma} = 1.6 \times 10^{44}$ ergs s$^{-1}$. In both panels the data are the same as in Fig. 1.
size and weak or absent variability, and HST-1 because its optical and X-ray flux increased while the TeV (HESS) flux remained constant or slightly decreased between 2003 and 2004. TeV emission from either the extended jet of M87 (Stawarz et al. 2004) or from hadronic processes in the giant elliptical galaxy itself (Pfrommer & Ensslin 2003) also do not agree with the observed TeV variability. Stawarz et al. (2005) used the fact that the TeV emission varies to set an upper limit on the actual TeV emission of knot A (lower than the lowest TeV flux observed) and, through this, a lower limit on its magnetic field.

A homogeneous core model is not favored because it cannot reproduce the core SED and is inconsistent with the unified scheme. A decelerating relativistic flow (GK03b) satisfies both the SED modeling and unification requirements. This is in contrast to both Cen A and NGC 6251, which have been modeled as homogeneous sources (Chiaberge et al. 2001, 2003). Neither of these sources is superluminal, suggesting a jet inclination larger than that of M87 and, in the context of a de-
