The luminosity function of white dwarfs and M dwarfs
using dark nebulae as opaque outer screens

Received ; accepted

Abstract. By using dark nebulae as opaque outer screens, the luminosity function of white dwarfs and M dwarfs has been studied. High-extinction areas towards the Orion A, Serpens and ρ Oph cloud complexes were observed, covering a volume corresponding to 464 pc$^3$ in the solar neighbourhood, complete to $M_V \sim 16.5$. Foreground stars were selected by $VRI$ photometry and photometric parallaxes.

The resulting foreground sample consists of 21 M dwarfs and 7 white dwarfs. The derived M-dwarf luminosity function is consistent with previous studies, showing no substantial up-turn beyond $M_V = 16$. The 7 white dwarfs imply a local density of $0.013 \pm 0.005$ M$_V$ pc$^{-3}$ ($\sim 15\%$ of the dynamical mass in the solar neighbourhood) supporting other recent results but obtained with a completely different method.

For the clouds, foreground-star data were used to derive independent cloud distances, while the background stars and a simple model of the Milky Way gave reliable cloud extinctions.

Key words: Stars: late-type - low-mass, brown dwarfs - luminosity function, mass function - white dwarfs - Galaxy: solar neighbourhood - stellar content

1. Introduction

The dark matter affects astronomy on all distance scales, single galaxies, groups of galaxies and the Universe as a whole. The dynamical mass in the solar vicinity has recently been determined from Hipparcos data to $0.076 \pm 0.015 M_\odot$ pc$^{-3}$ (Crézé et al. 1997), leaving little space for local dark matter, since the visible matter in form of stellar-like objects and the interstellar medium comprise $\sim 0.08 M_\odot$ pc$^{-3}$.

The stellar contribution to the local mass density derived by Jahreiss & Wielens (1997) is 0.039 M$_\odot$ pc$^{-3}$, which agrees within errors with most other recent figures (e.g. 0.042 ± 0.008 in Méra et al. 1996, 0.05 ± 0.01 in Kroupa et al. 1993 and 0.034 in Gould et al. 1996). Similar amounts of matter have been suggested to reside in the interstellar medium, $\sim 0.04$ M$_\odot$ pc$^{-3}$ (Haywood et al. 1997, Crézé et al. 1997, Bahcall et al. 1992 and references therein). However, present estimates of the local surface density of the interstellar medium range from $6$ to $13 M_\odot$ pc$^{-2}$, indicating a substantial uncertainty also in the space density.

The photometric surveys by Gould et al. (1996) and Kirkpatrick et al. (1994) give 0.011 M$_\odot$ pc$^{-3}$ for M dwarfs in the mass interval $0.1 - 0.5 M_\odot$. For the nearby stars the corresponding numbers are 0.013 and 0.015 M$_\odot$ pc$^{-3}$ respectively for Reid & Gizis (1997) (hereafter RG97) and Jahreiss & Wielens (1997). The discrepancy between the photometric and the nearby samples is significant and has been suggested to arise from unresolved binarity (Kroupa 1995) and structure in the $M_V$ vs $V - I$ relation that has not been taken into account (RG97). For the white dwarf (WD) mass density, the 0.003 WDs pc$^{-3}$ ($\sim 0.002 M_\odot$ pc$^{-3}$) given in Liebert et al. (1988) (hereafter LDM88), is less than 3% of the local dynamical mass. There are, however, recent investigations that point to a much higher mass hidden in WDs. Ruiz & Takamiya (1995) (hereafter RT95) derived, from a large proper motion survey, a factor three higher space density than in LDM88. A similar value was obtained by Oswalt et al. (1996) from WDs in binaries. This revision of the WD space density (supported also by this paper) indicates that as much as 15% of the local dynamical mass can be hidden in WDs.

Thus, although the bulk of the local mass seems to be identified, the role of the late M dwarfs and WDs in this context is still not clear and remains a question to discuss.

In this paper the subject is addressed in a survey of opaque nebulae, obtaining volume limited and dynamically unbiased samples of foreground M dwarfs and WDs. This method was first proposed by Herbst & Dickman (1983) and has previously been used by Jarrett (1992, 1995) and Jarrett et al. (1994) (hereafter JHD94), whose results will be discussed in Sect. 8.1. The present survey covers a volume corresponding to 464 pc$^{-3}$ in the solar neighbourhood and is complete to $M_V \sim 16.5$. The completeness limit is 2 magnitudes deeper than the previous surveys by Jarrett and the volume twice as large.

In § 2 the selection of the target clouds is described. § 3 outlines the observations and reduction procedures. The extinctions of the clouds are derived in § 4. The selection of foreground stars, including colour-colour analysis and photomet-
ric parallaxes is described in § 5. Constraints on our foreground sample obtained from other sources are given in § 6. The M-dwarf luminosity function (LF) and WD space densities, including corrections for multiplicity and galactic density gradients are derived in § 7. In § 8 the results of this paper are compared to other recent findings, with special emphasis on the dark cloud survey described in JDH94. The conclusions and some ideas for the future are given in § 9.

2. Selecting target clouds

A suitable target cloud should fulfill certain criteria. Its distance has to be known in order to match integration times to the faintest stars at the cloud’s edge. It has to be sufficiently opaque ($A_V \gtrsim 5$ mag) to screen out the vast majority of background stars and galaxies. The high extinction areas must be large enough to provide a reasonable number of foreground stars. It is also desirable to avoid the immediate neighbourhood of star-forming regions, since young overluminous stars within, or just in front of, the cloud may be mistaken as nearby older field M dwarfs.

The final selection includes the following cloud complexes, Orion A (southern part of L1641, 480 pc, $l = 213^\circ$, $b = -19^\circ$), Serpens ($\sim 4^\circ$ south from the Serpens cloud core, 200–250 pc, $l = 27^\circ$, $b = 3^\circ$) and two separate areas in $\rho$ Oph (L1688 and L1689, 160 pc, $l = 354^\circ$, $b = 16^\circ$). Cloud distances for the original selection were taken from Hilton & Lahulla (1995).

2.1. Cloud distances

The photometric distances and the total number of M dwarfs in front of Orion A indicate a distance of 400 rather than 480 pc. This result is consistent with the 390 pc in Anthony–Twarog (1982), derived from a subsample in the Warren & Hesser (1978) catalogue of stars associated with the Orion complex. In order to confirm this finding, the Hipparcos catalogue (ESA [1997]) was searched, resulting in parallaxes with standard errors less than 1 mas for 92 of the Warren stars, showing a well-defined peak at $\sim 400$ pc.

For Serpens, Straizys et al. ([1991]) gave a mean distance of 259 pc for 18 stars associated to the cloud. Their total sample consists of 99 stars, foreground, embedded and background. The low-extinction part of their sample indicates an extinction wall at $\sim 255$ pc. Of the 99 stars, 13 were measured by Hipparcos, revealing a few cases of misclassified luminosity classes, but basically confirming a distance of $\sim 260$ pc.

Eleven of the stars that were assigned a high probability to be associated with the $\rho$ Oph complex by Elias ([1973]) were identified in the Hipparcos catalogue and show a sharp peak at 150 pc.

The distances finally adopted in this paper are 400, 255 and 150 pc respectively to the Orion A, Serpens and $\rho$ Oph complexes. Note that these clouds are extended irregular objects far from being sheet-like or spherical. The distances above were derived from observations of optically visible stars, and therefore mainly probe the front edge of the cloud, which though is sufficient for the purpose of this paper. The errors in the cloud distances are expected to be on the order of 10%, giving a corresponding volume uncertainty of $\sim 30\%$.

3. Observations and reductions

The main body of data consists of $VRI$ photometry and was collected at the ESO NTT 3.55 m telescope at La Silla, Chile. The Serpens and $\rho$ Oph areas were observed in Jun28–Jul01, 1995 and cover 536 and 816 arcmin$^2$ respectively. The Orion A field, observed in Jan24–26 1996, covers 158 arcmin$^2$. The same instrumental setup was used in both runs, EMMI RED with CCD #36, TEK2048, each pixel corresponding to 0.27". The unvignetted field of view was 8.6' x 9.15'. Bias and flat-field corrections were done in a standard way with IRAF.

The transformations to the Johnson $V$ and Kron-Cousins $RI$ systems were based on standard stars selected from Landolt ([1992]). Since the observations were aimed at M dwarfs in the first place, care was taken to include the reddest dwarf stars in this list, G45-20 ($V = 4.00$), G156-31 ($V = 3.68$), G12-43 ($V = 3.48$), G10-50 ($V = 2.97$) and G44-40 ($V = 2.79$). The transformation to the standard system includes corrections for extinction, zero-point offsets and linear colour terms. The rms of the standard star residuals across the whole fitted colour range (0 < $V$ − $I$ < 4) is 0.02 mag in $VR$ and 0.03 mag in $I$.

3.1. Complementary NOT observations

For Orion A, part of the $VRI$ photometric candidates were measured in $J$ using ARNICA, a NICMOS3 near-IR array at the Nordic Optical Telescope (NOT), La Palma, in Sep 1996. The $J$ calibrations were made via standard stars provided by the ARNICA team (Hunt et al. [1995]). The Hunt transformation was adopted: $J_{ARNICA} = J_{NOT} +$ zero-point offset. The final 1σ error in the calibration of the $J$ magnitudes is 0.07 mag.

Low-resolution spectra of the two brightest WD candidates were obtained at the NOT in Nov 1997, using the ALFOSC, a low-resolution spectrograph/focal reducer combination instrument. Standard reductions were carried out with IRAF. It was not possible to apply a meaningful flux calibration, since the targets were always at airmasses between 2 and 3.5, leading to a substantial loss of light in the blue end of the spectra.

Since this survey was designed for detecting M dwarfs, the original $I$ exposure times were set rather short. The discovered WDs are bluer than the M dwarfs, resulting in uncertain $I$ magnitudes in the original data. The WD $J$ photometry was improved by ALFOSC observations at the NOT in Nov 1997. Again standard methods were used in the reductions.

All instrumental magnitudes were extracted by an empirical growth-curve method outlined in Festin (1997).

---

1 IRAF (Image Reduction and Analysis Facility) is distributed by National Optical Astronomy Observatories (NOAO), which is operated by the Association of Universities for Research in Astronomy, Inc., under contract with the National Science Foundation.
Fig. 1. $M_V$ at the peak in the through-shining background dwarf distribution as a function of the cloud’s visual extinction. The solid line is a polynomial least-square fit to the calculated points (asterisks). The rings mark the three reference fields at the extinction $A_V^1$ as derived in Fig. 3.

Fig. 2. The two-step extinction estimation. The dashed line is the main sequence. The solid line is the G0V reddening curve in Jarrett (1992). Each dot is a 0.5 mag step in $A_V$. The arrowed solid lines show the dereddening steps. The rings demonstrate the location of a fictitious set of stars.

The $M_V$ completeness limit of the survey was set by the $V$ data, as the magnitude at which the mean of the internal magnitude errors in a field equals 0.12 mag. This limit was justified by a star-count analysis in a previous study of the Pleiades (Festin 1998). Table I gives completeness limits and positions for all the observed fields.

4. Star counts and cloud extinctions

The extinction offsets relative to a reference field were derived for each field by the method of star counts (Dickman 1978). Since there are more background stars present in the I fields than in V or R, the I band was used for the star counts. The derived extinction in I is transformed to V by the relation in Winkler (1997), $A_V = 1.69A_I$.

In order to estimate absolute extinctions in the reference fields, a two-step method was used. A first estimate is obtained by shifting the blue edge of the bulk of the background stars along the reddening curve to the turn-off point (step 1 in Fig. 3). Since the majority of the background stars are reddened beyond the selected blue edge and their intrinsic colours are significantly bluer than the turn-off point ($V0/M0V$), the corresponding extinction offset is a crude lower limit of the real value. Although this lower limit is sufficient for most cases, it can be further refined (step 2 in Fig. 3) by using knowledge of the galactic structure and the LF. The Galaxy model of Bahcall & Soneira (1980) was used together with the LFs in Gould et al. (1996) ($M_V > 8$) and Scalo (1986) ($M_V < 8$) to derive the distribution of background stars as a function of cloud extinction. Figure 1 shows $M_V$ at the peak in the distribution of through-shining stars as a function of $A_{V\text{cloud}}$. The observed fields are at a low galactic latitude and suffer from high extinction. The background stars are therefore dominated by the thin-disk population, which makes the single-component disk of Bahcall appropriate to use. Uncertainties inherent in the model would mainly arise from systematic errors in the scale height vs spectral type relation. Such effects are small enough to be dominated by the variation in the LF of the background stars. Errors in step 2 that may arise from uncertainties in the LF are expected to be small, since the visible background stars predominantly consist of dwarfs between F and early K, i.e. stars for which the LF is well defined. Steps 1 & 2 are shown for the three reference fields in Fig. 3. Note that step 1 is a lower limit of the extinction derived independently from any assumptions of galactic structure or the LF. The error in step 2 is estimated to be $\sim 0.5$ mag. The derived extinction of the reference field, $A_{V\text{ref}} = A_V^1 + A_V^2$, is still only a lower limit, since we may now use the better estimate $A_{V\text{ref}}$ instead of $A_V^1$ in step 2, and iterate further. However, we restrict ourselves to two steps and regard the derived value to be a conservative lower limit with an error of $\sim 0.5$ mag in $A_{V\text{ref}}$.
4.1. Orion A

The whole area has a high roughly constant extinction. The two-step procedure was applied to the entire field, resulting in $A_V > 6.8$. From $^{13}$CO data in Fukui & Mizuno (1991) an independent value of $A_V \sim 7$ was derived using the $A_V - ^{13}$CO relation as in the Orion case, $V_R = -2$.

4.2. Serpens and ρ Oph

The fields were divided into overlapping squares of 1' x 1', separated by 15'. The number of stars within each square was summed in 0.1 mag bins, providing the extinction relative to the reference field.

The results for Serpens and ρ Oph respectively are $A_V > 6.9$ and $A_V > 2.4$. The same reference field was used for both areas in ρ Oph, since they are separated by only 1°.

The extinctions at the centres of the two areas in ρ Oph were estimated from $^{13}$CO column densities in Loren (1989). Using the same $A_V - ^{13}$CO relation as in the Orion case, $A_V \sim 11$ was deduced. The present survey gives a lower limit of $A_V \sim 7.5$. For the reference field, the $^{13}$CO gave $A_V \sim 3$, whereas this survey gives a lower limit of $A_V < 2.4$.

For both Orion A and ρ Oph, the lower limits from the present survey are in good agreement with independent values derived from $^{13}$CO data. This shows that reliable lower limits on the extinction can be obtained directly from the $VRI$ data. The Serpens extinction, derived using the same method as for Orion and ρ Oph, is therefore likely to be a reliable lower limit as well.

### Table 1. Observed areas and completeness limits. The photometric system is $RI$ Kron-Cousins (KC) and $V$ Johnson (J)

| Field | RA (2000) | DEC (2000) | $l$ | $b$ | $V_{KC}$ | $R_{KC}$ | $V_{J}$ | $M_{V}$ |
|-------|-----------|------------|-----|-----|---------|---------|--------|--------|
| Serpens A | 18:27:29.1 | -3:42:21 | 26.8931 | 3.6223 | 22.1 | 23.2 | 24.2 | 17.2 |

5. Selecting foreground stars

To really make use of the clouds as screens, crowded regions must be avoided. A conservative upper limit on the average surface density of stars brighter than the completeness limits was set at 4 per arcmin$^2$. The remaining areas are for ρ Oph 689 arcmin$^2$ and for Serpens 412 arcmin$^2$, 84 and 77% of the respective original fields. For Orion A the entire field (158 arcmin$^2$) is sufficiently sparse.

Figures of the target areas, including selected foreground stars and excluded regions are shown in App. A.

### 5.1. Colour-colour analysis

The reddened background stars separate from the foreground main sequence at $V-R = R-I = 0.9$ (M0V), resulting in two parallel sequences separated by ~0.5 mag in $V-R$ (Fig. 1). All stars within 0.15 mag of the empirical main sequence were considered as foreground candidates by colour and had their photometric parallaxes measured (see Sect. below). The resulting foreground M-dwarf sample is shown in Figs. 4 and 10. For ρ Oph a number of bright stars fall in-between the main sequence and the reddened background stars. This is not a result of systematic photometric errors, since in the same field there are many stars lying perfectly on the reddening sequence. These objects are preferably found in ρ Oph W. Since they are absent from the Serpens area at a lower galactic latitude, reddened M giants are not a likely explanation. Most probably they are recently formed stars, still embedded in the nebula (see also Sect. 6 and Fig. 10).
As photometric WD candidates those objects lying approximately in the region of the WDs in Bergeron et al. (1997) were considered (Fig. 7). These objects are distinctly separated from other stars and form a well-defined isolated group. Note that the reddest WDs systematically fall below the empirical sequence. This is probably caused by the increasingly different spectra in WDs as compared to the standard stars towards cooler temperatures.

5.2. Photometric parallaxes

Photometric distances, although suffering from a large spread in the $M_V$ vs $V-I$ relation, are used here as an additional tool for cleaning out background stars. As a bonus, cloud distances get independent consistency checks. Note the lack of stars between 400 and 500 pc for Orion A in Fig. 8, clearly indicating that $d = 480$ pc is an overestimate of the distance.

To check possible foreground extinction, stars within 7° from the target areas were selected from the UBV catalogue Mermilliod (1987) via SIMBAD. $E_{B-V}$ was determined by the Q method for stars earlier than A0 (see e.g. Mihalas & Binney (1981)). Later stars with known spectral types were also used. For all three areas it was concluded that foreground extinction is too small to affect the results of this paper.

5.2.1. M dwarfs

Each object was assigned a mean, min and max distance. The mean distance is derived from the composed $M_V$ vs $V-I$ relation in RG97. Min and max values come from their corresponding $1\sigma$ spread. A histogram of the mean distances to the colour-colour foreground candidates marked in Figs. 4-6 is shown in Fig. 8. Stars consistent with being foreground objects...
6. L. Festin: The luminosity function of white dwarfs and M dwarfs

Fig. 7. Photometric WD candidates. Symbols are as in Figs. 4. New symbols: The shaded area outlines the WDs of Bergeron et al. ([1997]). Errorbars are 1. J-113 is a WD from JDH94

Fig. 8. Photometric mean distances to the photometric foreground M-dwarf candidates. The solid bars show the adopted cloud distances

are distinctly sorted out. The final sample of probable foreground M dwarfs consists of 21 stars (Table 2).

5.2.2. White dwarfs

Photometric distances were estimated via a linear least-square fit of $M_V$ vs $V - I$ of the WDs in Bergeron et al. ([1997]) with parallax errors less than 30%:

$$M_V = 12.67 + 2.48 (V - I) \quad (\sigma = 0.3)$$

This functional form provides only a rough estimate of the WD absolute magnitude. One should keep in mind that there are WDs like ESO439-26 (Ruiz et al. [1995]) that do not follow this relation in the least.

It is possible, although unlikely, that these WD candidates are reddened background stars. Since the background extinction at the position of the WD candidates in all cases is estimated to exceed 6.8 mag in $V$ (Table 2), a through-shining star of the same colour as our reddest WD candidate ($V - I \sim 1.5$) would have an unreddened colour $(V - I)_0 < -1.2$. There are no such stars. Suppose that they are indeed early-type stars shining through low-extinction windows. A B1V star behind OrionA would then have to be at a distance of about 0.5 Mpc to fit the observed magnitudes, i.e. 160 kpc above the galactic plane, which is unrealistic. The simplest answer is that these objects are indeed foreground WDs.

5.2.3. Spectroscopic confirmation of white dwarfs

In Fig. 9, spectra taken at the NOT of the two brightest WDs are compared with two spectrophotometric standard stars. Hz21 is a He-rich WD of type DO, while G93-48 is of type DA. The serpwd3 spectrum is classified as type DB, since it only shows HeI lines (Dreizler & Werner [1996]). The second WD is serpwd1, showing a rather noisy spectrum due to its faint magnitude. However, the absence of prominent spectral features in combination with its magnitude and colour makes it a very likely WD.

6. Constraints on foreground candidates from other surveys

The Orion A area (L1641) has been extensively surveyed in the infrared (Strom et al. [1989] [1993]; Ali & Depoy [1995]). In
In \( \rho \) Oph, the western area was entirely covered in \( JHK \) in a survey by Barsony et al. (1997). There are 30 overlapping sources brighter than our completeness limits, including all three foreground candidates in this area (ophmd3–5 in Table 3). In Fig. 10 the appearance of the overlapping sample in \( VRI \) is compared to \( IJK \). Ophmd3 and 4 are confirmed as foreground by the additional \( JHK \) data. For ophmd5, the three independent \( JHK \) measurements are not consistent, implying either variability or a problem in the photometry. The fact that ophmd5 does not keep its position relative to the bulk of the background stars between \( VRI \) and \( IJK \) supports it being a foreground star of spectral type about M6V.

The \( \rho \) Oph E area was covered in \( VRI \) by Jarrett (JDH94 thesis). Both our candidates in this area (ophmd1–2) have magnitudes consistent with theirs, and are considered as possible foreground stars in Jarrett (1992). Ophmd2, though, was rejected from the foreground candidates in JDH94. Both stars are slightly redder than the main sequence in \( V-R \) (Fig. 6), but are still regarded as foreground stars. See Sect. 8.3 for a thorough comparison to Jarrett’s results.

In our Serpens field, no complementary photometric data could be found.

7. The luminosity function

A simplified version of the \( V_{\text{max}} \) method (Felten 1976), outlined below, was used to derive the LF. In a photometric survey each star has a maximum distance, \( d_{\text{max}} \), at which it
Fig. 10. Overlapping near-IR sources. The two earliest foreground candidates are represented in the upper panel by mean values of the $I-K$ magnitudes given in Barsony et al. (1997), Strom et al. (1995) and Greene et al. (1992). Individual values were used for the latest candidate, triangle (Barsony), pentagram (Strom) and box (Greene). Dashed lines are the corresponding main sequences and the solid lines show the empirical reddening sequences.

still can be detected. The corresponding maximum volume, $V_{\text{max}}$, is defined by the survey area and $d_{\text{max}}$. Each star’s contribution to the LF is then $V_{\text{max}}^{-1}$. In order to compensate for galactic density gradients and reduce the derived LF to the solar neighbourhood, $V_{\text{max}}$ must be replaced by $V_{\text{max,gen}}$, a generalized volume (Tinney 1993):

$$V_{\text{max,gen}} = \Omega \int_0^{d_{\text{max}}} r^2 e^{-r\sin|b|/h} dr,$$

where $\Omega$ denotes the angular area of the field, $h$ the disk scale height and $b$ the galactic latitude. The distances involved here are small enough to neglect the radial density gradient in the Galaxy. Both the M-dwarf and WD distribution was approximated by the old disk population, with a scale height $h = 350$ pc (Bahcall & Soneira 1980). Deriving $V_{\text{max}}$ is a trivial operation in a dark cloud survey, since for all stars brighter than the completeness limit (in absolute magnitude) $d_{\text{max}} = d_{\text{cloud}}$. This is an important point of this paper, the survey volume not being derived through a colour-magnitude relation having a large cosmic spread. Table 3 gives the physical and generalized values of the foreground volumes.

The last column in Table 3 shows the weighted count for each foreground star deduced as $V_{\text{max}}/V_{\text{max,gen}}$. Errors in the distances to the clouds are expected to be on the order of 10%, implying volume uncertainties of $\sim 30\%$. This uncertainty has not been included in the further analysis.

Table 3. Observed volumes in pc$^3$

| area      | $V_{\text{max}}$ | $V_{\text{max,gen}}$ |
|-----------|------------------|-----------------------|
| Orion A   | 285              | 216                   |
| Serpens   | 193              | 188                   |
| $\rho$ Oph | 66               | 60                    |
| total     | 544              | 464                   |

Table 4. The foreground M-dwarf sample binned into 1-mag bins in $M_V$. The 2nd last bin is complete in 70% of the volume and the last bin in 26%. No correction for incompleteness has been applied.

| bin          | $N$ | Cum $N$ | $N_{\text{gen}}$ | Cum $N_{\text{gen}}$ |
|--------------|-----|---------|------------------|----------------------|
| $M_V$        |     |         |                  |                      |
| 10-11        | 3   | 3.67    | 3.67             | 4.49                 |
| 11-12        | 4   | 4.82    | 8.49             | 6.19                 |
| 12-13        | 2   | 2.41    | 10.90            | 4.46                 |
| 13-14        | 7   | 7.85    | 18.75            | 9.30                 |
| 14-15        | 2   | 2.64    | 21.39            | 4.20                 |
| 15-16        | 1   | 1.32    | 22.71            | 2.62                 |
| 16-17        | 2   | 2.41    | 25.12            | 3.06                 |
| 17-18        | 0   | 0       | 25.12            | 0.80                 |

7.1. M dwarfs, main sequence

The majority of foreground stars are early-type M dwarfs, $2.5 < V - I < 3.2$, reflecting the well-known peak in the LF. The low number of M dwarfs (21) implied a rather coarse binning in the LF. Table 3 gives the LF in 1-mag bins, while in Fig. 11 2-mag bins were chosen. The agreement with previously determined LFs is satisfactory.

For stars brighter than $M_V = 10$ ($\sim M1V$) the number that is lost due to saturation starts to become significant. These stars are therefore not considered further.

The large spread in the faint bins in Fig. 11 illustrates the present uncertainty in the stellar LF. The Poissonian 1 $\sigma$ uncertainties in Jahreiss & Wielen (1997) and RG97 are about 30% in the last two bins.

7.1.1. Lost companions

RG97 found that the number of lost unresolved companions approximately is compensated for by distant stars spread into a magnitude limited sample via Malmquist bias. This will not be
7.2. White dwarfs

The sample of WDs is too small to derive any details in the WD LF. Seven WDs were found, 0.015 \( \pm 0.006 \) pc\(^{-3} \) (Poissonian errors), which is a significantly higher number than expected from LDM88 \( (0.003 \) pc\(^{-3} \)), but in better agreement with RT95 and Oswalt et al. \( (1996) \), who both give \( \sim 0.008 \) pc\(^{-3} \). These numbers will be discussed in more detail in Sect. 8.2.

Fig. 11. The M-dwarf luminosity function. The dashed line is the system LF and the solid line the single-star LF derived after binary correction. Diamonds and stars show the LF of Kirkpatrick et al. \( (1994) \) and Gould et al. \( (1996) \) respectively. Asterisks and circles outline the LF of the nearby stars in RG97 and Jahreiss & Wielen \( (1997) \) respectively. The error bars show Poisson errors of the generalized counts before binary correction. Errors in the LF arising from uncertain cloud distances have not been included (expected to be \( \sim 30\% \)). The incompleteness in the last bin (see Table 4) has not been corrected for the case in this survey, since the foreground sample is strictly volume limited and there is a dark cloud preventing distant stars from interfering. The number of lost companions was estimated from the binary distribution in the nearby stars in RG97. After applying the correction for galactic structure 10 companions were expected to have been lost. These were distributed as the lost binary companions in Fig. 12 of RG97 and added to our system LF. The resulting companion-corrected LF is shown in Fig. 11 and Table 4.

8. Discussion, comparison to other works

For the M-dwarf part, the agreement with other photometric surveys is satisfactory (Fig. 11). It is clear that any contamination of the M-dwarf sample from background stars and/or stars associated with the clouds must be small and that the opaquenebula method works reliably also in a purely photometric version, provided that the photometry is sufficiently accurate.

The main advantage in comparison to other methods is that the survey volume does not rely on photometric parallaxes. Even though the individual absolute magnitudes do suffer from cosmic spread in the colour-magnitude relation, each star’s contribution to the space density does not.

If the distance to the cloud is not known a priori, it can either be estimated from the photometric distances of the foreground objects or by their integrated number in a well-known part of the LF. In this context it would be useful to obtain more data for foreground stars brightwards of the peak in the LF at \( M_V = 12 \).

The derived samples are volume limited and unaffected by dynamical bias. Finally, the dark clouds effectively screen background galaxies and giant stars from the foreground population.

Among the drawbacks are that the selected foreground objects in general will be too distant for binaries to be resolved and therefore the derived LF must be corrected for by an a priori known binary distribution function. The dark clouds are not evenly spread across the sky, which means that the available areas are restricted. On the other hand, they do provide a tool for probing areas near the Milky Way plane.
8.1. The Jarrett paper

We compare our result with that of JDH94. The generalized volume sampled in that paper is 52 pc$^3$ ($\rho$ Oph) + 101 pc$^3$ (Taurus), totally 153 pc$^3$. A striking difference as compared to our survey is their excess of late foreground candidates, seen also in the Barnard 5 survey (Jarrett 1993). The comparison here was made in $\rho$ Oph E, where part of our surveys overlap. Five of their six foreground candidates that were cross identified lie perfectly on the reddening sequence in our data and are definitely not foreground objects (Fig. 12). Since our data for the bright J43 are consistent, the photometric calibration is likely to be correct. A possible explanation of the colour discrepancy is that these sources were spread into the JDH94 foreground sample as a result of their lower signal-to-noise ratio. Our data reach $\sim$ 2 magnitudes deeper than JDH94. It may also be that the JDH94 photometry is subject to systematically discrepant corrections for atmospheric correction, since their data were acquired at high air masses ($\sim$ 2, Jarrett, priv comm.). The tendency that very faint stars, barely measurable, scatter into the M-dwarf zone is seen also in our data, and was the main reason for including objects only to the completeness limit and not all the way down to the detection limit of the survey, about 1 mag fainter.

8.2. White dwarfs

A local number density of 0.015 ($\pm$0.006) WDs pc$^{-3}$ was derived from the 7 WDs discovered in this survey. This is a factor 5 more than predicted from LDM88. RT95 found 0.008 ($\pm$0.003) WDs pc$^{-3}$ in a proper motion survey, consistent with our result, but as in our case the numbers are small. An interesting result is that Ruiz et al. (1993) found a factor 2 more stars with $\mu > 0.5$" yr$^{-1}$ than present in LHS (Luyten 1956) for overlapping areas. The LDM88 sample was drawn from LHS and would also be affected by this proposed incompleteness, a fact that may explain the discrepancy in the LDM88 WD density as compared to more recent results.

Oswalt et al. (1996) used yet another approach and arrived at 0.0053$^{+0.0035}_{-0.0007}$ WDs pc$^{-3}$ for WDs in wide binaries. They added the single-WD LF in LDM88 (0.0023 WDs pc$^{-3}$) and concluded that the total space density of WDs in the solar neighbourhood is 0.0076$^{+0.0037}_{-0.0007}$ WDs pc$^{-3}$. Our results and RT95 show that the LDM88 sample is likely to suffer from a rather large incompleteness, suggesting that adding 0.0023 WDs pc$^{-3}$ to the binary part results in a substantial underestimation of the total WD space density.

Our sample of WDs includes neither wide nor narrow binaries, except possible double WDs. If we add our WD density to the Oswalt binaries the result is 0.02 ($\pm$0.007) WDs pc$^{-3}$, corresponding to 0.013 ($\pm$0.005) M$_{\odot}$ pc$^{-3}$ if we assume a mean mass of 0.65 M$_{\odot}$ per WD. The WD fraction of the dynamical mass would then be 17 ($\pm$ 7) %. Objects like ESO 439-20 (RT95) and WD 0346+246 (Hambly et al. 1997) suggest that the WD density may be even larger.

The results of the MACHO micro lensing experiment (Alcock et al. 1997) have given a mean mass of the lensing objects of $\sim$0.5 M$_{\odot}$, although strongly model dependent. The MACHO mass density in the solar neighbourhood is on the order of 0.005 M$_{\odot}$ pc$^{-3}$, which in fact is consistent with the proposed increase of the WD space density. However, more definite results will have to await a larger volume limited sample of WDs.

9. Conclusions and future prospects

The space density of M dwarfs and WDs has been studied as volume limited samples in front of dark high extinction nebulae, a method that efficiently reduces the impact of Malmquist bias, since the survey is volume limited and the LF not depending on individual photometric distance estimates. Areas towards the molecular cloud complexes $\rho$ Oph, Serpens and Orion A were observed. The survey covers a volume corresponding to 464 pc$^3$ in the solar neighbourhood, complete to $M_V \sim 16.5$. In total 21 M dwarfs and 7 WDs were identified as foreground objects.

Although details are hard to resolve due to the limited sample, our M-dwarf LF is consistent with previous photometric results, and after binary correction also with the nearby stars. Our survey does not show any signs of the reported upturn in the faintest magnitude bins in the previous dark cloud surveys (Jarrett 1992, 1995; Jarrett et al. 1994), and we conclude that their excess of faint M dwarfs is probably caused by their larger photometric errors.

The unexpected appearance of as many as 7 WDs compared to the 1.4 estimated from the WD space density in LDM88 is perhaps the most interesting result of this paper. The derived space density is 0.015 ($\pm$0.006) WDs pc$^{-3}$. By combining our sample with the binary WDs in Oswalt et al. (1996) the final estimate is 0.02 ($\pm$0.007) WDs pc$^{-3}$, implying a mass density of 0.013 ($\pm$0.005) M$_{\odot}$ pc$^{-3}$. This means that the WDs may contribute by as much as 15–20% to the local dynamical mass. No doubt this subject is not yet settled and deserves further investigation.

The method of opaque nebulae has indeed proved to be efficient in identifying foreground M dwarfs and WDs. Concerning the latter, any nebula that provides a colour excess $E_{V-I} > 2$ ($A_V > 5$) ensures that also the bluest main sequence stars get a reddened colour beyond the reddest known WDs ($V-I \sim 1.5$). Already for Orion A the available area is $\sim$ 50 times larger than our field, enclosing a volume that would host $\sim$ 150 WDs and $\sim$ 550 M dwarfs, numbers that certainly are sufficient for a more detailed analysis of the corresponding LFs. The increased availability of large field CCDs and CCD mosaics provides the ideal tools for this kind of survey. We have also shown that the distance to the clouds and the cloud extinction may be reliably derived from the $VRI$ data alone, an important point if a future large-scale survey of this kind is to be carried out.
Acknowledgements. I wish to thank the ESO OPC for allocating observing time for this exciting project. This work was supported by the Nordic Optical Telescope Scientific Association and the Swedish Natural Science Research Council (NFR). This research has made use of the Simbad database, operated at CDS, Strasbourg, France.
