A B S T R A C T

Exercise can exert anti-inflammatory effects in an intensity-dependent manner; however, the mechanisms mediating these effects are continually being established. Programme Death Receptor-1 (PD-1) is a membrane bound receptor that maintains immune tolerance by dampening immune cell interactions, such as those mediated by cytotoxic T-cell lymphocytes (CD8+). The aim of this study was to characterise sub-populations of CD8+ T-cells with regards to their expression of PD-1 before and immediately after exercise. Interleukin (IL)-6, soluble PD-1 (sPD-1) and its ligand (sPD-L1) were also quantified in plasma. Eight individuals (mean ± SD: age 29 ± 5 years; BMI 24.2 ± 3.4 kg m⁻²; VO₂max 44.5 ± 6.4 ml kg⁻¹ min⁻¹) undertook two time and energy-matched cycling bouts in a counterbalanced study design: one of moderate intensity (MOD) and a bout of high intensity interval exercise (HIIE). Both MOD and HIIE increased the number, but not the proportion of circulating CD8+ T-cells, with no differences between trials. Within the CD8+PD-1+ pool, the expression of PD-1 increased on central memory cells following HIIE only (fold change: MOD 1.0 vs HIIE +1.4), as well the concentration of CD8+PD-1+ memory cells within the circulation (cells/uL: MOD -0.4 vs HIIE +5.8). This response composed a very small part of the exercise-induced CD8+ lymphocytosis (Pre-Ex: 0.38% to Post-Ex: 0.69%; p < 0.05). sPD-L1 and IL-6 concentration increased in tandem following MOD and HIIE (r = 0.57; P = 0.021), with a reciprocal decline in sPD-1 observed. The current data demonstrate that PD-1+CD8+ lymphocytes were mobilised following both MOD and HIIE. Both the number of central memory CD8+ T-cells expressing PD-1 and the expression level on these cells were increased following HIIE only. This intensity-dependent phenotypic response, in conjunction with increased circulatory sPD-L1 may represent an aspect of the anti-inflammatory response to exercise and warrants further investigation.

1. Introduction

Regular exercise can lower systemic inflammation in both healthy and clinical populations (Hamer et al., 2014, 2012). The cumulative impact of acute inflammatory responses that follow individual exercise bouts is believed to be a major stimulus for creating this anti-inflammatory environment, which appears more marked at higher exercise intensities (Wang et al., 2012). The mechanisms underpinning these effects are primarily attributed to: 1) increased release of myokines from skeletal muscle (e.g. IL-6), 2) phenotypic shifts in cell composition (blood monocytes and adipose tissue-resident macrophages) and 3) a reduction in the expression of membrane-bound immune receptors that govern immune cell activity, migration and inflammatory cytokine production (Gleeson et al., 2011). The independent contribution of these factors is far from clear and a myriad of other mechanisms likely contribute. For example, programmed-death receptor-1 (PD-1) is an immune checkpoint receptor with an established role in regulating circulating inflammatory signals (Coles et al., 2014) but is yet to be...
extensively characterised following acute exercise or periods of exercise training.

PD-1 is a membrane-bound receptor primarily expressed on lymphoid cells that provides a ‘brake’ or checkpoint for the immune system (Francisco et al., 2010). PD-1 interacts specifically with its co-stimulatory ligands, PD-Ligand 1 (PD-L1) and 2 (PD-L2), which are ubiquitously expressed. These ligand-receptor interactions result in reduced immune cell activity and thus provide an anti-inflammatory environment that is critical for the maintenance of immunological homeostasis. It is now well established that aberrant expression of PD-1 can dramatically affect immune function and health (Barriosiska et al., 2018; Granados et al., 2017; Iijima et al., 2017; Ilie et al., 2016; Li et al., 2014; Lu et al., 2017; Nováková et al., 2015). High expression of PD-1 on certain immune cells (e.g. cytotoxic T-cells (CD8+)) is known to severely suppress immune function in numerous blood and tissue cancers (Ilie et al., 2016; Lu et al., 2017; Nováková et al., 2015). Conversely, reduced expression of PD-1 has been documented on CD8+ T-cells from patients with autoimmune diseases, such as type-1 diabetes (Granados et al., 2017; Iijima et al., 2017), rheumatoid arthritis (Li et al., 2014) and Psoriasis (Barriosiska et al., 2018), driving autoimmunity. These studies underpin the central role that PD-1 has in regulating immunological homeostasis, and yet, alterations in PD-1 expression have only recently been explored for the first time in the context of exercise (Gustafson et al., 2017).

Gustafson et al. (2017) reported that a single session of maximal cycling marginally increased the blood composition of PD-1+ T-cells within CD4+ (–3.15%) and CD8+ (–5.53%) subsets (Gustafson et al., 2017). It is well documented that the influx of lymphocytes into the circulation during exercise is largely driven by CD8+, rather than CD4+ T-cells (Turner et al., 2016), and is dependent on the intensity of the bout (Campbell et al., 2009). The composition of this CD8+ T-cell pool is markedly altered to favour increased immune surveillance for antigen-presentation at secondary lymphoid organs and inflamed tissues (Dhabhar et al., 2012). PD-1 is primarily expressed on memory cells (Claireaux et al., 2018) and functions to limit the inflammatory response by increasing apoptosis of antigen-specific effector T-cells (Francisco et al., 2010); however, how antigen-specific frequencies of CD8+ T-cells expressing PD-1 change following exercise bouts of different intensities is currently unknown. Further to the membrane-bound forms of PD-1 and PD-L1, soluble (s) PD-1 and sPD-L1 are detectable within the extracellular environment of blood (Chen et al., 2018; Wei et al., 2018), but have yet to be explored in the context of exercise, despite their role in modulating T-cell activity (Kuijpers et al., 2006; Song et al., 2011).

Our collective understanding of both membrane and soluble PD-1 in the context of exercise and immunity is currently lacking, particularly regarding how exercise alters the specific memory phenotype of T-cells expressing PD-1, their physiological relevance in blood (i.e. number of cells expressing PD-1) and relationships to sPD-1 and sPD-L1. Characterisation of these responses could provide important insight into the anti-inflammatory effects that underpin exercise, with important subsequent implications for health and immunity. The aim of the present study was to characterise changes in the expression of PD-1 in circulating naïve, central memory, effector memory and terminally differentiated CD8+ T-cells following two time and energy-matched bouts of moderate and high intensity cycling. To better understand the link between cellular PD-1 and plasma sPD-1/sPD-L1 in the context of inflammation, sample-matched IL-6 measurements were made.

2. Materials and methods

2.1. Participants

Following ethical approval from the University of Worcester Research Ethics Committee, eight healthy males (mean ± SD: age 29 ± 5 years; BMI 24.2 ± 3.4 kg m⁻²; VO₂max 44.5 ± 6.4 ml kg⁻¹ min⁻¹) were recruited to take part in the study. All participants completed questionnaires addressing health history and habitual levels of weekly physical activity using the International Physical Activity Questionnaire (IPAQ). All participants gave their written informed consent and the study was carried out in accordance with the Declaration of Helsinki (2008). Participants were non-smokers and reported that they had not taken any antioxidant vitamin supplements or anti-inflammatory drugs for 8 weeks prior to the laboratory visit. In addition, participants reported to be free from any viral or bacterial infections for at least 4 weeks prior to taking part. Participants were also required to refrain from any strenuous physical activity, consumption of alcoholic beverages or caffeine for two days prior to each experimental session.

2.2. Experimental sessions

Participants reported to the laboratory on three separate occasions, all carried out under stable climatic conditions (18–20 °C and humidity between 45 – 55%). Following a 30-min period of rest, resting heart rate (RS400, Polar Electro, Finland), height (Seca Alpha, Hamburg, Germany) and body mass (Tanita, Tokyo, Japan) were determined on each visit. On participants first visit, cardiorespiratory fitness (VO₂max) was assessed using a ramp test to exhaustion on an electromagnetically braked cycle ergometer (Lode Excelsius Sport, Groningen, Netherlands). Workload commenced at 100 Watts and was increased by 30 Watts every 4 min. Heart rate and oxygen uptake was assessed continuously using a breath-by-breath system (Cortex Biophysik Metalyzer, Germany). VO₂max was determined if two of the following criteria were met in conjunction with a plateau in oxygen consumption after an increase in workload: volitional exhaustion; a respiratory exchange ratio of ≥1.15; heart rate within 10 beats min⁻¹ of the age-predicted maximal heart rate (220 - age); a drop in cadence below 60 revolutions per minute (Howley et al., 1995). A final obtained value of rate of oxygen consumption relative to body mass was accepted as VO₂max (ml kg⁻¹ min⁻¹) and used to inform the workload for the subsequent two trials.

At least one week following the VO₂max test, participants undertook two energy and time-matched cycling trials in a counterbalanced order: a moderate intensity bout of continuous cycling at 60% VO₂max for 58 min (MOD) and a bout of high intensity interval exercise (HIIE), consisting of 10 x 4-min intervals at 85% VO₂max, with 2-min rest intervals. Both trials took place following an identical overnight fast at least one week apart. In both studies, oxygen uptake was assessed continuously to maintain target VO₂ and ensure equal energy expenditure between MOD and HIIE. Ratings of perceived exertion (RPE) were measured every 6 min during the trials.

2.3. Blood sampling

In both MOD and HIIE, a catheter (Appleton Woods, Birmingham, UK) was inserted into the antecubital vein of the arm prior to exercise to obtain a baseline sample after 30 min of rest (Pre-Ex). Additional blood samples were taken immediately (Post-Ex), 30 min (Post-Ex+30) and 60 min (Post-Ex+60) following completion of each cycling trial. At Pre and Post+0 timepoints, 18 ml of blood was drawn into two separate vacutainer tubes containing potassium ethylene diaminetetraacetic acid (EDTA) (Becton, Dickson Company; Oxford, UK) for independent isolation of peripheral blood mononuclear cells (PBMCs) and plasma. At Post-Ex+30 and Post-Ex+60 timepoints, 9 ml of blood was collected for plasma isolation only. The catheter was flushed every 30 min with isotonic saline solution (0.9% sodium chloride) to prevent blood clotting.

2.4. Plasma analyses

A cytometric bead array technique was used to quantify plasma interleukin (IL)-6 on a BD C6 Accuri Flow Cytometer (BD Biosciences, Berkshire). Plasma PD-L1 (BMS2212; sensitivity: 0.6 pg/ml, intraassay CV: 2.1%, interassay CV: 3.4%) and PD-1 (BMS2214; sensitivity 1.14 pg/
ml, intraassay CV: 3.2%, interassay CV: 6.4%) were quantified using commercially available ELISA kits (Thermo Fisher Scientific, Loughborough). All concentrations were corrected for changes in plasma volume based upon established criteria (Dill and Costill, 1974).

2.5. Isolation of CD8+ T-cells

Whole blood from Pre-Ex and Post-Ex timepoints only were used to isolate PBMCs using density gradient centrifugation. Blood was diluted 1:1 with Hanks Balance Salt Solution (HBSS), and then layered carefully on top of Histopaque 1077 (Sigma, Dorset), before centrifuging at 400g for 40 min at 21°C. The PBMC layer was aspirated and then washed three times with HBSS, by centrifuging steps at 300g for 10 min. Approximately 3 million cells per time point were then enriched for CD8+ T-cells by negative selection using MACS® bead separation (Miltenyi Biotec, Surrey, UK). PBMCs were incubated with a biotin-antibody cocktail (anti-CD4, CD15, CD16, CD19, CD34, CD36, CD56, CD123, TCRγ/δ, and CD235a), followed by a CD8+ T-cell microbead cocktail (anti-CD14, CD61 and anti-biotin) for 10 min at 4°C, with intermittent washes using column wash buffer (PBS supplemented with 0.5% bovine serum albumin and 2 mM EDTA, pH = 7.2). CD8+ cells from both time-points were eluted by negative selection using three separate MiniMACS LD-column passes, using an excess of de-gassed column buffer (Miltenyi Biotec, Surrey, UK). CD8+ T-cell enrichment was confirmed by flow cytometry staining analysing the CD3+CD8+ lymphocyte population (>95% purity).

2.6. Flow cytometry

Approximately 1,000,000 viable PBMCs were used for determination of CD8+ T-cell subsets and expression of PD-1 using four-colour flow cytometry (Guava EasyCyte, Millipore UK Ltd, Hertfordshire, UK). Cells were incubated with fluorescently conjugated antibodies – CD3-FITC (clone: HIT3a), CD279-PE (clone: EH12.2H7), CD45RA-PerCP (clone: HI100), CD27-APC (clone: M-T271) (Biolegend, Cambridge, UK) for 30 min at 4°C followed by intermittent washes with PBS for 5 min at 300 x g. Compensation was adjusted daily by using single stained controls and gates established using fluorescent minus one controls. Confirmation of non-specific antibody binding was determined by using isotope-matched controls.

Flow cytometry data were analysed using GuavaSoft 3.1 (Millipore UK Ltd, Hertfordshire, UK). Briefly, lymphocytes were gated on forward versus side scatter and CD3+ and CD8+ T-cell proportions used to determine MACS enrichment efficacy. MACS enriched CD8+ T-cells were identified as naïve (CD27+ CD45RA+), central memory (CD27+ CD45RA-), effector memory (CD27- CD45RA+), or terminally differentiated effector memory cells (TEMRA: CD27+ CD45RA-) accordingly (Di Mitri et al., 2011). Within each sub-population, mean fluorescence intensity (MFI) and percentage positive cells was established for PD-1 (CD279). The percentage of PD-1+ cells were used with whole blood cell counts to determine the circulating number of PD-1+ cells in peripheral blood for each sub-population, and adjusted for changes in plasma volume.

2.7. Statistical analysis

The Shapiro Wilk test was used to check for normality in scale data at all time points. Variables with a non-normal distribution were log transformed if necessary. Changes in sub-populations of immune cells, CD8+ cells expressing PD-1, PD-1 expression levels and plasma markers (sPD-1, sPD-L1 and IL-6) were assessed over time (Pre, Post, Post-Ex+30 and Post-Ex+60) and between Trials (MOD, HIIE) by a 2 x 2 (cellular data) or 2 x 4 (plasma data) repeated-measures analysis of variance (ANOVA) or Wilcoxon Signed Rank Tests, depending on variable normality. Post hoc analysis of any ANOVA interaction effects (Trial x Time) were performed by a test of simple effects by pairwise comparisons, with Bonferroni correction. Mann Whitney U tests were performed to determine differences between MOD and HIIE at different timepoints for non-parametric data. Effect sizes for main effects and interaction effects of ANOVA are presented as partial eta2 (η2p), using Cohen’s definition of η2p of 0.01, 0.06 and 0.14 for ‘small’, ‘medium’ and ‘large’ effects respectively (Cohen, 1988). Pearson correlation and Spearman rank were used to assess the relationship between parametric and non-parametric data respectively. All values are presented as means ± standard deviation or error (indicated throughout manuscript). Data were back transformed for ease of presentation in figures. Statistical significance was accepted at the P < 0.05 level. Statistical analyses were performed using SPSS (PASW Statistics, release 23.0, SPSS Inc., Chicago, IL, USA).

3. Results

3.1. Physiological response during MOD and HIIE

The physiological responses during each exercise bout are reported in detail elsewhere (Wadley et al., 2019). Briefly, Peak VO2 and RPE were significantly greater in HIIE compared to MOD (P < 0.00001), but there were no statistically significant differences in mean VO2 and energy expenditure.

3.2 Changes in lymphocyte sub-populations after MOD and HIIE in blood

Changes in lymphocyte and CD8+ T-cell subset concentrations are reported in Tables 1 and 2 respectively. Total lymphocyte concentration increased after both trials (P = 0.014). Within the lymphocyte pools, CD3+ (P = 0.011) and CD8+ (P = 0.006) T-cell concentrations also increased, with no differences between MOD and HIIE for any lymphocyte subset. Within the CD8+ T-cell pool, naïve (P = 0.050), central memory (P = 0.036), effector memory (P = 0.050) and TEMRA (P = 0.012) all increased following MOD, but only TEMRA increased following HIIE (P = 0.049). There were no statistically significant differences in CD8+ T-cell concentrations between MOD and HIIE at any timepoint.

3.4. Changes in sPD-1, sPD-L1 and IL-6 in response to MOD and HIIE and associations with cellular variables

Changes in plasma levels of sPD-1 and sPD-L1 are reported in Fig. 3. sPD-L1 concentration increased immediately (MOD: Z = -2.38, P = 0.017, η² = 0.35 and HIIE: Z = -2.38, P = 0.017, η² = 0.35) after exercise and was elevated Post-Ex +30 and Post-Ex +60 (MOD: Z = -2.52, P = 0.012, η² = 0.40 and HIIE: Z = -2.52, P = 0.012, η² = 0.40). A decrease in sPD-1 concentration was observed immediately after both trials (MOD: Z = -2.52, P = 0.012, η² = 0.40 and HIIE: Z = -2.24, P = 0.025, η² = 0.31), and remained below Pre-Ex levels at Post-Ex +60 (MOD: Z = -2.38, P = 0.017, η² = 0.35 and HIIE: Z = -2.10, P = 0.036, η² = 0.28). IL-6 concentration increased above Pre-Ex at all post-exercise timepoints in both trials (Time x Condition effect: F (3) = 15.5, P < 0.0001, η² = 0.66), with the magnitude of increase significantly greater following HIIE (Time x Condition effect: F (3) = 7.0, P < 0.001, η² = 0.47). A positive correlation was noted between concentrations of IL-6 and PD-L1 Post-Ex (r = 0.57; P = 0.021). No statistically significant correlations were noted between plasma and cellular variables.

Fig. 1. Changes in the concentrations of CD8⁺ T-cell subsets (naïve, central memory, effector memory and terminally differentiated effector memory) before (black bars) and after (white bars) MOD (panel A) and HIIE (panel B). Values are means ± standard error. * indicates significant differences relative to Pre-Ex: *p < 0.05. + indicates a significant difference between MOD and HIIE: p < 0.05.

4. Discussion

The current study highlights that single bouts of moderate and high intensity interval exercise evoke an increase in the circulating concentration of PD-1⁺ CD8⁺ T-cells in young, untrained, healthy males. As part of this response, the number of PD-1⁺ CD8⁺ central memory T-cells increased following HIIE only, with PD-1 expression also increased on these cells. Plasma sPD-L1 and sPD-1 increased and decreased respectively after both trials, with a positive association noted between IL-6 and PD-L1. Taken together, these results highlight a phenotypic specific change in the regulation of PD-1 on CD8⁺ T-cells that is exercise intensity-dependent. Furthermore, we highlight for the first time that soluble forms of the PD-1 receptor and ligand are reciprocally regulated, and was elevated Post-Ex +30 and Post-Ex +60 (MOD: Z = -2.52, P = 0.012, η² = 0.40 and HIIE: Z = -2.52, P = 0.012, η² = 0.40). A decrease in sPD-1 concentration was observed immediately after both trials (MOD: Z = -2.52, P = 0.012, η² = 0.40 and HIIE: Z = -2.24, P = 0.025, η² = 0.31), and remained below Pre-Ex levels at Post-Ex +60 (MOD: Z = -2.38, P = 0.017, η² = 0.35 and HIIE: Z = -2.10, P = 0.036, η² = 0.28). IL-6 concentration increased above Pre-Ex at all post-exercise timepoints in both trials (Time x Condition effect: F (3) = 15.5, P < 0.0001, η² = 0.66), with the magnitude of increase significantly greater following HIIE (Time x Condition effect: F (3) = 7.0, P < 0.001, η² = 0.47). A positive correlation was noted between concentrations of IL-6 and PD-L1 Post-Ex (r = 0.57; P = 0.021). No statistically significant correlations were noted between plasma and cellular variables.

A single session of exercise induces large haemodynamic and β2-adrenergic receptor-mediated changes that drive the mobilisation of lymphocytes into the bloodstream (Graff et al., 2018). This response is not uniform, with lymphocytes such as CD8⁺ T-cells with high antigen specificity, activation and migratory capacity being preferentially mobilised (e.g. effector T-cells) (Campbell et al., 2009). The general consensus is that this response is highly functional, and operates to enhance immunosurveillance and tissue remodelling in the period after exercise (Campbell and Turner, 2018). As a result, exercise immunology research has largely focussed on characterising CD8⁺ T-cells with regards to their activation, migration and effector functions (e.g. cytotoxicity). Conversely, relatively little attention has been paid to negative regulators of T-cell function, which might act to suppress or modulate this...
with higher effector functions, such as TEMRA, which are typically the
(Fig. 2), with progressive loss of the PD-1 receptor documented on T-cells
of PD-1 is primarily limited to memory T-cells (Gustafson et al., 2017)
migration into tissues (Brunner-Weinzierl and Rudd, 2018). Expression
cell activation (Keir et al., 2007), differentiation (Ahn et al., 2018) and
intensity of exercise, given that the HIIE protocol controlled for both total
duration and the energy cost of exercise, compared to MOD.

The only previous study to investigate changes in immune checkpoint
evolution after exercise reported an increase in the percentage of PD-
+, but not CTLA-4 + CD8+ T-cells after maximal cycling exercise
(Gustafson et al., 2017). A compositional increase in PD-1 + CD8+ T-cells
was not observed in the present study, and as such, suggests that pref-
erential trafficking of PD-1 + CD8+ T-cells may only increase in response
to maximal cycling exercise. Notably however, the current study subse-
quently phenotyped CD8+ T-cells, as well as determining physiologically
relevant changes within the bloodstream in response to exercise.
Importantly, the increase in CD8+ PD-1 + central memory T-cells
composed a very small component of the total exercise-induced
lymphocytosis (Pre-Ex: 0.38% to Post-Ex: 0.69%). Our data therefore
provide novel insight into changes in PD-1 within T-cells after different
intensities of exercise, both with regards to cell phenotype and physio-
logically relevant changes within the circulation. Both are undoubtedly
important in understanding changes in T-cell function and their redis-
tribution after exercise. Future work should take this approach to
establish whether a small increase in CD8+ PD-1 + central memory T-cells
has physiological relevance in governing the immune responses to ex-
ercise. For a more complete picture, other immune checkpoints, such as
CTLA-4 should be explored in this context.

Another novel finding from the present study was that exercise
evoked an increase in the circulating plasma concentration of sPD-L1 and
decrease in sPD-1 immediately, and up to 60 min post-exercise (Fig. 3).
These responses were not dependent on the intensity of exercise, nor
associated with changes in membrane-bound PD-1 expression or circu-
lating PD-1+ cell numbers. The exact cellular origin and functional ac-
tions of these soluble immune checkpoints have yet to be fully
established. Both sPD-1 (primarily released from T-cells) and sPD-L1
(released from dendritic cells and tissues) (Gu et al., 2018) can be

![Fig. 2. Changes in the expression of PD-1 in CD8+ T-cells and their subsets before (black bars) and after (white bars) MOD (panel A) and HIIE (panel B). Values are means ± standard error. * indicates a significant difference relative to Pre-Ex: *p < 0.05. # indicates significantly higher expression levels in memory T-cells subsets, compared to naïve and TEMRA; ####p < 0.0001.](Image)

![Fig. 3. Changes in the concentrations of PD-L1 (A) and PD-1 (B) before (Pre-Ex) and after (Post-Ex, Post-Ex-30 and Post-Ex-60) MOD (grey bars) and HIIE (white bars). Values are means ± standard error. * indicates a significant difference relative to Pre-Ex: *p < 0.05. # indicates a significant difference relative to Post-Ex: #p < 0.05.](Image)
produced through alternate mRNA splicing (Nielsen et al., 2005) or cleavage of the membrane-bound form directly (Zanto et al., 2011). There is some evidence to suggest that sPD-1 and sPD-L1 may act in an antagonistic manner, such that sPD-1 competes and sPD-L1 engages with membrane-bound PD-1 (Gu et al., 2018; He et al., 2005). This is supported by studies suggesting that sPD-1 enhances (Yuan et al., 2004) and sPD-L1 inhibits (Li et al., 2016) T-cell activity. From the current study, we can therefore speculate that an increase in sPD-1 after exercise may form a component of the anti-inflammatory response to exercise, acting to engage and activate membrane-bound PD-1. This is supported by a reduction in PD-1 concentration and a positive association between post-exercise sPD-L1 and IL-6 (Fig. 4), a pleiotropic cytokine with a role in anti-inflammatory signalling (Ellingsgaard et al., 2019). It must be noted that the cellular mechanisms mediating the removal of sPD-1 from the circulation in this short timeframe after exercise is far from clear at present. Further work is needed to fully understand the kinetics of soluble immune checkpoints after exercise and their functional role is regulating communication between immune cells and tissues.

PD-1 and other immune checkpoints have attracted significant attention in biomedical and clinical research because of their profound impact on regulating immune tolerance in diseases associated with immune dysfunction. Immune checkpoint expression is commonly elevated in anti-inflammatories and conversely reduced on T-cells from patients with various autoimmune diseases (Ilie et al., 2015) and conversely reduced on T-cells from patients with various autoimmunity diseases (Bartosinska et al., 2018; Granados et al., 2017; Iijima et al., 2017; Li et al., 2014). How an increase in PD-1 expression after acute exercise translates into changes with regular exercise training, particularly in these populations is currently unknown. It is conceivable that exercise-induced upregulation of PD-1 expression could enhance immune tolerance in patients with certain autoimmune diseases; however, more work is needed to investigate the effects of regular exercise on immune checkpoints in a clinical context.

5. Conclusion

The results of the current study have highlighted phenotypic and physiological relevant changes in PD-1+ CD8+ T-cells after bouts of MOD and HIIE. PD-1+ CD8+ T-cells are mobilised in response to both types of exercise, however, central memory CD8+ T-cells expressing PD-1 increased after HIIE only. Despite this being a very small component of the exercise-induced lymphocytosis, PD-1 expression also increased on these cells, highlighting a specific phenotypic response associated with exercise at higher intensities. We have also highlighted for the first time that soluble immune checkpoints are altered in response to exercise, with sPD-L1 and sPD-1 increasing and decreasing up to 60 min after exercise respectively. Further work is needed to examine the changes in membrane and soluble immune checkpoints after exercise, and their relevance to regulating health in the context of autoimmunity.
