ACCESS

ABSTRACT: Colloidal quantum dots (CQDs) are a promising gain material for solution-processed, wavelength-tunable lasers, with potential application in displays, communications, and biomedical devices. In this work, we combine a CQD film with an array of nanoantennas, made of titanium dioxide cylinders, to achieve lasing via bound states in the continuum (BICs). Here, the BICs are symmetry-protected cavity modes with giant quality factors, arising from slab waveguide modes in the planar CQD film, coupled to the periodic nanoantenna array. We engineer the thickness of the CQD film and size of the nanoantennas to achieve a BIC with good spatial and spectral overlap with the CQDs, based on a second-order transverse-electric (TE)-polarized waveguide mode. We obtain room-temperature lasing with a low threshold of approximately 11 kW/cm² (peak intensity) under 5-ns-pulsed optical excitation. This work sheds light on the optical modes in solution-processed, distributed-feedback lasers and highlights BICs as effective, versatile, surface-emitting lasing modes.

KEYWORDS: colloidal quantum dots, lasing, bound state in the continuum, slab waveguide, distributed-feedback cavity, dielectric nanoantennas

Solution-processed lasers, such as those made using colloidal quantum dots (CQDs),1–7 colloidal quantum wells,8–11 and perovskites,12–14 possess wide spectral tunability and a compact, flexible form factor and are of interest for display, communications, sensing, and biomedical applications. Significant material innovations have led to continuous-wave (CW), solution-processed lasers at or close to room temperature, with a threshold pump intensity ranging from ~100 W/cm² to ~10 kW/cm².2,3,8,13 Breakthroughs derived from innovations in optical design have also been reported.10,15

In general, a low-threshold laser requires not only an optical cavity with minimal absorption or radiation loss, and hence a high quality (Q) factor, but also good spatial and spectral overlap between the cavity mode and gain material to ensure efficient light–matter interaction. In previous solution-processed lasers, distributed-feedback (DFB)2–4,12,13 and Fabry–Pérot1,8,9 cavities have been employed extensively. A Fabry–Pérot cavity can possess a high Q factor and can position the gain material at the field maximum; however, fabrication of a high-Q device is challenging because of the large number of layers required and the need for precisely controlled layer thicknesses. A DFB cavity, on the other hand, typically consists of a gratings made of a dielectric, coated with a solid film of gain material. The spatial mode-gain overlap extends laterally across the entire device, and the in-plane reflections (as a result of the periodic variation in the refractive index) can produce a high Q factor when the number of periods is large. Commercially available DFB lasers made of III–V semiconductors rely on the fundamental DFB mode, which involves a phase shift of \( \pi \) per period, to achieve edge lasing. In contrast, reported solution-processed lasers have largely relied on the second-order DFB mode, which contains a phase shift of \( 2\pi \) per period. While optical feedback is in plane, a second-order DFB can couple light out of plane via diffraction to achieve lasing in the normal direction.

Upon closer examination, the second-order DFB involves two distinct band-edge modes with different field distributions, representing the two ways a standing wave could be formed from two counter-propagating waves in the grating. This is illustrated for transverse-electric (TE)-polarized modes in Figures 1a and 1b, which plot the y-component of the electric field of the standing wave along a grating. The field of the mode in Figure 1a has the same symmetry as that of a plane wave at normal incidence (e.g., with respect to a \( y-z \) plane cutting in the middle of a unit cell); the mode can thus couple to the far field by diffraction. In contrast, the mode in Figure 1b has a different symmetry than the plane wave and therefore...
cannot couple to the far field in the normal direction. With a lower radiation loss, the mode in Figure 1b should have a higher Q factor. In fact, its Q factor could be infinite in theory for an ideal system without any absorption, scattering, or diffractive losses. Such a mode is known as a symmetry-protected bound state in the continuum (BIC).\textsuperscript{16–20}

Taking advantage of the impressive Q factors, BICs have been utilized to achieve lasing in III–V semiconductors,\textsuperscript{21–27} colloidal quantum wells,\textsuperscript{11} perovskites,\textsuperscript{14,28} and organics.\textsuperscript{29,30} Early reports on CQD lasers,\textsuperscript{2} however, did not differentiate between a BIC and a diffractively coupled band-edge mode. In the present work, we show that lasing occurs through symmetry-protected BICs, by experimentally determining the dispersion diagram (i.e., the photonic band structure).\textsuperscript{16–20} In addition, we engineer the CQD film thickness so that the grating-CQD slab supports not only first-order but also second-order waveguide modes (Figure 1c). We show that the BIC arising from a second-order waveguide mode gives a lower lasing threshold, thanks to better spatial mode-gain overlap. This leads to room-temperature lasing under 5-ns-pulsed optical excitation with a threshold peak intensity of approximately 11 kW/cm\textsuperscript{2}. The threshold is similar to those of other reports of DFB lasers since, with the relatively high refractive index of TiO\textsubscript{2} (n ∼ 2.5), Mie resonances can be excited efficiently in the cylinders, transforming them into nano-antennas.\textsuperscript{33–35} This enhances the optical intensity in the near field, thus allowing stronger light–matter interaction. The CQDs with chloride ligands (see Methods in the Supporting Information for details). These CQDs can achieve amplified spontaneous emission (ASE) under stripe pump at low thresholds; Figure S2 in the Supporting Information shows a CQD film reaching ASE at ∼35 kW/cm\textsuperscript{2}. The refractive index of these CQDs is ∼1.9 at visible wavelengths, as measured using spectroscopic ellipsometry. Upon spin-coating, the CQD film is approximately 300 nm thick on a plain (grating-free) area, as measured using a profilometer. The sample is then capped with a layer of polydimethylsiloxane (PDMS, ∼1 mm thick), whose refractive index is similar to that of the quartz substrate (n ∼ 1.5).

Given the thickness and refractive indices, the combined CQD-TiO\textsubscript{2} slab is able to support first- and second-order waveguide modes. For both modes, at a given frequency, the grating periodicity can be tuned so that the longitudinal (in-plane) component of the wave vector gives a phase delay of 2π per period of the grating. Under these conditions, counter-propagating waves form a standing wave, resulting in either a band-edge mode radiating in the normal direction via diffraction or a symmetry-protected BIC with no (or suppressed) radiation in the normal direction. The two modes have a slight energy difference owing to the different localizations of the field in the grating giving rise to a band gap at the Γ point in the dispersion diagram.

Figure 1. (a, b) Schematic showing two distinct second-order DFB modes with transverse-electric (TE) polarization: (a) diffraction-coupled band-edge mode; (b) bound state in the continuum (BIC). The y-component of the electric field (E\textsubscript{y}) is plotted for the standing wave along the x-direction of the grating. The direction of the electric field (E\textsubscript{z}) is indicated for the standing wave as well as the plane wave incident on the structure in the normal direction. The field of a BIC has a different symmetry compared to that of the plane wave, so a BIC is decoupled from the far field and has zero radiation loss. The solid and dashed arrows for the k vector in parts a and b denote allowed and forbidden radiation in the normal direction, respectively. CQD: colloidal quantum dot. (c) Sketch of E\textsubscript{y} along the transverse (z) direction for the first- and second-order slab waveguide modes supported in the grating coated with a relatively thick layer of CQDs. (d) Device structure of the CQD laser in this work. The TiO\textsubscript{2} cylinders are 120 nm in height, and the period of the square array, a, is tuned with the cylinder diameter, keeping the gap between the cylinders fixed at 40 nm. The CQD film is about 300 nm in thickness. Optical measurements are taken in the x–z plane with TE polarization.
To determine experimentally the photonic band structure of the sample, we measure the reflectance spectrum resolved in both wavelength and angle of incidence (or reflection), by projecting the back focal plane image through the slit of a spectrometer (see Methods in the Supporting Information for details). Figure 2a shows the reflectance spectrum of a CQD-coated TiO$_2$ nanoantenna array with a cylinder diameter of 340 nm, when the incident light is TE-polarized. We observe bands arising from diffractive coupling of the first- and second-order waveguide modes, as well as vanishing reflectance at normal incidence near the band gaps, indicating the presence of BICs. To understand the optical modes better, we run a numerical simulation to obtain the more detailed dispersion diagram in Figure 2b. Here, we see salient features of several BICs at the $\Gamma$ point ($0^\circ$), where reflectance is inhibited since incident plane waves cannot couple to the BICs due to symmetry incompatibility.

The arrows in Figure 2b indicate the two BICs of interest, and eigenmode calculations give their mode profiles (Figures 2c and 2d for the side and top views of a unit cell, respectively). As expected, the BIC at $\lambda \sim 740$ nm arises from a first-order TE-polarized waveguide mode, while the BIC at $\lambda \sim 630$ nm originates from a second-order waveguide mode. The in-plane polarization vectors (Figure 2d) reveal a...
The larger the cylinder diameter (i.e., the larger the grating period), the more red-shifted the optical modes, as the required in-plane propagation constant becomes lower for a given phase delay per period. For the cylinder array presented in Figure 2, the second-order BIC is in the desired spectral range (λ ∼ 630 nm). To match the gain peak with the first-order BIC, however, the resonances must be blue-shifted. We find that when the cylinder diameter is reduced to 280 nm (period to 320 nm), the resonant wavelength of the first-order BIC is shifted to λ ∼ 630 nm; see Figure S4 in the Supporting Information for a series of PL spectra for diameters ranging from 280 to 340 nm. Figures 3b and 3c contain the TE-polarized PL spectra of the CQD-coated arrays, with cylinder diameters of 280 and 340 nm, respectively, showing efficient coupling of the CQD PL to the various waveguide modes. In particular, we observe clear symmetry-protected BICs with a radiation node in the normal direction, namely the first- and second-order BICs in Figures 3b and 3c, respectively. The light emitted by the CQDs that is coupled to the BICs cannot radiate into the far field due to a mismatch in the field symmetry and is thus trapped in the cavity, providing efficient optical feedback for the CQDs. Furthermore, comparing Figures 3c and 2a, we notice that the PL map reflects the photonic bands more clearly than the reflectance map, potentially because of the additional enhancement in CQD emission by the Purcell effect.

To characterize lasing, we photoexcite the sample with a pulsed laser at λ = 535 nm (pulse width ∼ 5 ns, repetition rate ∼ 1250 Hz). We perform back focal plane (BFP) imaging to...
capture the PL intensity as a function of the emission angle, to a maximum angle of \(\sim 33^\circ\) limited by the numerical aperture of the collection objective (NA = 0.55). Figure 4a shows the BFP image of the unpolarized PL from the CQD-coated array with a cylinder diameter of 340 nm, supporting the second-order BIC. Here, we see the first- and second-order diffraction bands coupled to the CQD PL, with the first-order diffraction (i.e., second-order DFB) approaching the normal. As mentioned earlier, passing the BFP image through the slit of a spectrometer yields the angle- and wavelength-resolved PL spectrum. Figure 4c shows the PL analyzed spectrally along the \(y\)-axis of the BFP. At a pump fluence of 46 \(\mu J/cm^2\), we see some enhancement of the PL intensity at the second-order BIC, but the PL coupled to other bands is of a similar order of magnitude in intensity.

As we increase the pump fluence to 54 \(\mu J/cm^2\), the BFP image (Figure 4b) and the PL spectrum (Figure 4d) change dramatically. The PL intensity at the BIC increases by about 40 times, and lasing occurs at \(\lambda = 626\) nm. Closer examination of the BFP image above the lasing threshold (Figure 4b, side panel) reveals a donut-shaped bright spot in the normal direction; see the angular distribution in Figure S5 in the Supporting Information. Intuitively, the donut shape is a result of suppressed radiation in the strict normal direction for the BIC but lasing radiation in the vicinity of the BIC, where a good balance exists between a high Q factor and an accessible radiation channel. Such a radiation pattern is characteristic of lasing through BICs based on dipoles oscillating normal to the waveguide-based BICs we observe here have electric fields similar to those of out-of-plane magnetic dipoles. Lastly, the light-in light-out curve (Figure 4e) and the PL spectra integrated across angles (Figure 4f) indicate a lasing threshold of \(\sim 54 \mu J/cm^2\), corresponding to a peak intensity of about 11 kW/cm\(^2\) for 5-ns pulses.

On the other hand, we also observe a lasing threshold of \(\sim 150 \mu J/cm^2\) for the array with a cylinder diameter of 280 nm, via the first-order BIC; see Figure S6 in the Supporting Information for details. We note from Figure 2c that the field antinodes for the first-order BIC lie mainly inside the \(\text{TiO}_2\) cylinder, while the field antinodes for the second-order BIC lie also in the CQD gain medium. As a result, the first-order BIC has poorer spatial overlap with the CQDs, which leads to a higher lasing threshold.

The threshold of 11 kW/cm\(^2\), observed from the second-order BIC, is comparable to that of the CW lasing of the same type of CQDs reported earlier.\(^3\) In the previous work, a 200 \(\times\) 200 \(\mu m\) magnesium fluoride (MgF\(_2\), \(n \sim 1.4\)) grating was used on a MgF\(_2\) substrate cooled to about \(-20^\circ C\).\(^5\) Here, we use a smaller 50 \(\times\) 50 \(\mu m\) \(\text{TiO}_2\) nanoantenna array on a quartz substrate and at room temperature but photoexcited using 5-ns pulses at 1250 Hz instead of at CW. While it is unclear whether the previous CW study involved a diffractive band-edge mode or a BIC, in this work, we identify the lasing mode specifically as a BIC, based on a second-order slab waveguide mode. This type of mode possesses not only a giant Q factor but also good spatial overlap with the CQDs, allowing us to achieve low-threshold, room-temperature nanosecond lasing.

Although our study suggests that the high-Q BIC is more favorable for lasing than the diffraction-coupled band-edge mode, which is also observed in a previous study on plasmonic nanoparticle arrays,\(^3\) it is important to note that more work is necessary to ascertain if BICs would indeed dominate (i.e., lead to a lower lasing threshold) under all circumstances, particularly given that the spatial mode-gain overlap can be better for the diffractive band-edge mode (Figure 1a) compared to the BIC (Figure 1b). Provided the spectral mode-gain overlap is similar, the competition between the Q factor and the spatial overlap would be interesting to explore.

We advocate for characterization of lasing modes in detail, including the dispersion diagram and radiation pattern, for second-order DFB lasers in the future. Understanding the nature of the lasing cavity should be helpful not only for device optimization but also for applications. For instance, BIC lasers are promising as compact, on-chip sources of optical vortex beams,\(^{14,39-41}\) with their far-field radiation carrying well-defined topological charges (i.e., polarization rotating about the beam axis; see Figure 2d). Vortex microlasers at optical frequencies offer potential benefits in optical communications and quantum information processing.

In conclusion, we report a low-threshold laser at room temperature, consisting of a \(\sim 300\)-nm-thick film of CQDs covering a square array of \(\text{TiO}_2\) cylindrical nanoantennas. Lasing is achieved from high-Q modes known as BICs, arising from first- and second-order TE-polarized slab waveguide modes, excited in the CQD-\(\text{TiO}_2\) structure and coupled to the periodicity of the nanoantenna array. The second-order BIC, in particular, gives a low lasing threshold of approximately 11 kW/cm\(^2\) under 5-ns-pulsed optical pumping, thanks to a high Q factor and good spatial mode-gain overlap. In addition, for what is conventionally termed a second-order DFB mode, we differentiate between a BIC and a band-edge mode coupled to diffraction. We show that BICs are the modes responsible for lasing in the (near) normal direction in our system and encourage researchers in the field to collectively verify if BICs, with their extraordinarily high Q factors, are the dominant lasing modes in second-order DFB lasers. Finally, we highlight the potential application of BIC lasers, with their exotic radiation patterns, as sources of optical vortex beams for communications and information processing.
