Dynamic heterogeneity in amorphous materials

(Dated: January 28, 2013)

Amorphous solids are mechanically rigid while possessing a disordered structure similar to that of dense liquids. Recent research indicates that dynamical heterogeneity, spatio-temporal fluctuations in local dynamical behavior, might help understanding the statistical mechanics of glassy states.

THE PUZZLE POSED BY AMORPHOUS MATERIALS

From the point of view of statistical physics, glasses are mysterious materials. Glassy materials possess a mechanical rigidity which is similar to the one of a crystalline material. In a crystal, rigidity is a direct consequence of the long-range periodic order: it is not possible to move a single particle in a perfect crystal (while preserving the crystalline order) without also moving an extensive set of neighbors, see Fig. 1(a). While mechanically rigid, glasses do not seem characterized by any type of long-range order, see Fig. 1(b), they actually resemble ordinary dense liquids. The comparison between crystals and glasses suggests that perhaps a more subtle symmetry breaking takes place during the formation of a glass, one that is not obvious to the naked eye. This conundrum has been a long-standing issue in condensed matter physics [1, 2].

Experimentally, one faces the fundamental difficulty that liquids approaching the glass transition (for example by decreasing temperature) become too viscous to flow on experimental timescales, and fall out of thermal equilibrium without encountering any reproducible thermodynamic phase transition. It is of course tempting to interpret this dramatic dynamic slowing down as originating from an underlying phase transition or critical point. Near an ordinary critical point, large scale spatial fluctuations develop, as the density fluctuations in the example shown in Fig. 1(c), and the dynamics slows down [3]. However, no such fluctuations are detected near the glass transition (see Fig. 1(b)). Therefore, finding convincing evidence of an underlying phase transition governing the physics of amorphous materials would represent an important progress in this field.

In the last decade these questions have also come up in the field of soft condensed matter, in which disordered structures known as “jammed” materials [4] (foams, emulsions, colloidal gels, sandpiles) stop flowing when their density becomes large, without possessing long-range crystalline order, just like molecular glasses. J.D. Bernal [5] in the 60’s was one of the first physicists to suggest that disordered atomic fluids and granular packings could be investigated using similar tools and, perhaps, understood using similar theoretical concepts—an idea that has since remained highly popular [6].

Dynamic heterogeneity in amorphous materials is a complex collective phenomenon, which shares more similarities with ordinary critical points than the featureless structure shown in Fig. 1(b) would suggest.

WHAT IS DYNAMIC HETEROGENEITY?

The concept of dynamic heterogeneity as a key feature that characterizes disordered materials has slowly emerged from experimental studies of highly viscous molecular liquids approaching the glass transition. In these systems, relaxation spectra measured through mechanical or dielectric probes span a very broad range of relaxation times and are strongly nonexponential. This suggests the existence of wide distributions of relaxation rates.

What is the microscopic origin of these broad distributions? Looking again at the disordered structure in Fig. 1(b), it is natural to imagine that the presence of structural disorder implies that atoms in different environments move differently. The physical picture is that, at any given time, different regions in a liquid might relax in a different manner and at a different rate, thus producing broad distributions of relaxation times. However, when the system is close to the glass transition but not yet a glass, particles constantly move and rearrange, and so the distinction between different spatial environments can only hold over a finite duration.

Dynamic heterogeneity refers to the existence of transient spatial fluctuations in the local dynamical behavior. Dynamic heterogeneity is observed in virtually all disordered systems with glassy dynamics [7].

Direct confirmation of the heterogenous character of the dynamics stems for instance from computer simulations of simple models of supercooled liquids, see Fig. 2.
FIG. 1: (a) A periodic crystalline structure does not flow because preserving the crystalline order requires moving an extensive set of particles. (b) A mechanically rigid glassy structure exhibits neither the long-range order of a crystal nor the large scale density fluctuations observed at an ordinary critical point. (c) Large scale critical density fluctuations near the critical point.

Whereas the averaged displacement of a particle in a given time window of width $t$ is a smooth increasing function of $t$, the time signals for individual particles shown in Fig. 2 have two important characteristics.

(i) They are highly intermittent in time, being composed of a succession of long periods of time where particles vibrate around well-defined locations, separated by rapid “jumps”. The waiting times separating successive jumps are statistically broadly distributed.

(ii) The trajectories differ widely from one particle to another in the same system at the same time. Some particles undergo many jumps and move large distances while some other particles are nearly immobile over the entire time window.

As all other features related to dynamic heterogeneity, such observations cannot be made from ensemble-averaged measurements. Indeed, the characterization of dynamic heterogeneity requires the development of experimental techniques that are not only sensitive to averaged or typical behaviour, but can also resolve the fluctuations. For theoreticians, the existence of dynamic heterogeneity implies that fluctuations need to be taken into account in the description of transport properties. Therefore, materials close to a glass transition differ qualitatively from ordinary fluids, where fluctuations can typically be neglected.

The intermittency of single-particle trajectories, while a clear indication of spatio-temporal fluctuations, do not tell us how these fluctuations are correlated in space. This point was first addressed in pioneering works using four-dimensional NMR and direct probing of fluctuations at the nanoscopic scale using atomic force microscopy techniques in polymeric glasses. Direct visualizations of molecular trajectories are not yet possible but recent, very elegant, experimental approaches using single molecule spectroscopy are getting close to it. Direct visualisation is possible for different types of glasses, such as colloidal and granular assemblies. All these spatially resolved measurements indicate that extended regions of space indeed transiently behave as fast and slow regions.

FIG. 2: Time resolved squared displacements of individual particles in a simple model of a glass-forming liquid. The average behavior is shown as the smooth full line. Individual trajectories are composed of long periods of time during which particles vibrate around well-defined positions, separated by rapid jumps that are widely distributed in time and occur at different times and frequencies for different particles.

NEED FOR HIGH-ORDER DYNAMIC CORRELATION FUNCTIONS

We have described dynamic heterogeneity as spatial variations in the local relaxation rate. Although hard to detect in an experiment, these fluctuations are easily observed in a computer simulation, where the position of each particle is known at each time step. In Fig. 3 we show an example of the visualisation of the spatially
heterogeneous dynamics in a simple model of a supercooled liquid, in two spatial dimensions. This visualization shows the existence of spatially extended “domains” where the amplitudes of single-particle displacements are correlated. Remember that these domains have no obvious counterpart in the density fluctuations, Fig. 1(b), and only appear when dynamics is considered. However, the spatial fluctuations in Fig. 3 are obviously reminiscent of the critical fluctuations in Fig. 1(c), with one major difference: while a thermodynamic quantity (the density) becomes critical in ordinary critical phenomena, fluctuations in glassy systems [16, 17]. Like in critical phenomena, if one makes the hypothesis that there exists a single dominant length scale \( \xi \) then one expects that for large distances the correlation function \( G_4(r; t) \) decays as

\[
G_4(r; t) \approx \frac{A(t)}{r^p} e^{-r/\xi_4(t)},
\]

with \( p \) a critical exponent. It is also natural to define the susceptibility associated with the correlation function

\[
\chi_4(t) = \int d^d r G_4(r; t).
\]

If the prefactor \( A(t) \) in Eq. 3 is known, the susceptibility \( \chi_4(t) \) can be used to infer the typical number of particles involved in the correlated motion shown in Fig. 3. That is, \( \chi_4(t) \) may be interpreted as the “volume” of the correlated clusters.

Further, \( \chi_4(t) \) can also be obtained from the fluctuations of the total mobility \( C(t, 0) = \int d^d r c(r; t, 0) \), through

\[
\chi_4(t) = N[(C(t, 0)^2) - (C(t, 0))^2].
\]

In practice, this formula allows an efficient measure of the degree of dynamical heterogeneity, at least in computer simulations and in those experiments where the dynamics can be spatially and temporally resolved. As long as \( c(r; t, 0) \) appropriately quantifies atomic motion, \( \chi_4(t) \) can be measured in a variety of systems, serving as a basis for fair comparisons of the extent of dynamical heterogeneity and has become a central tool in characterizing dynamic heterogeneity in amorphous materials [18].

by the correlation function

\[
G_4(r; t) = \langle c(r; t, 0)c(0; t, 0) \rangle - \langle c(r; t, 0) \rangle^2,
\]

which depends only on the time \( t \) and the distance \( r = |r| \) as long as the ensemble average, denoted with brackets, is taken at equilibrium in a translationally invariant system; \( G_4(r; t) \) is known as a ‘four-point’ dynamic correlation function because it measures correlations of motion between time 0 and time \( t \) arising at two points, 0 and \( r \).

The analogy with fluctuations in critical systems becomes clear in Eq. 2 if one considers the mobility field \( c(r; t, 0) \) as playing the role of the order parameter for the transition, characterised by nontrivial fluctuations and correlations near the glass transition. This analogy is now fully exploited in modern theoretical treatments [2].

The above definition of a real-space correlation function of the mobility represents a vital advance in the characterization of dynamical heterogeneity. For instance, it allows the language of field theory and critical phenomena to be used in studying dynamical fluctuations in glassy systems [16, 17]. Like in critical phenomena, if one makes the hypothesis that there exists a single dominant length scale \( \xi \) then one expects that for large distances the correlation function \( G_4(r; t) \) decays as

\[
G_4(r; t) \approx \frac{A(t)}{r^p} e^{-r/\xi_4(t)},
\]

with \( p \) a critical exponent. It is also natural to define the susceptibility associated with the correlation function

\[
\chi_4(t) = \int d^d r G_4(r; t).
\]

If the prefactor \( A(t) \) in Eq. 3 is known, the susceptibility \( \chi_4(t) \) can be used to infer the typical number of particles involved in the correlated motion shown in Fig. 3. That is, \( \chi_4(t) \) may be interpreted as the “volume” of the correlated clusters.

Further, \( \chi_4(t) \) can also be obtained from the fluctuations of the total mobility \( C(t, 0) = \int d^d r c(r; t, 0) \), through

\[
\chi_4(t) = N[(C(t, 0)^2) - (C(t, 0))^2].
\]

In practice, this formula allows an efficient measure of the degree of dynamical heterogeneity, at least in computer simulations and in those experiments where the dynamics can be spatially and temporally resolved. As long as \( c(r; t, 0) \) appropriately quantifies atomic motion, \( \chi_4(t) \) can be measured in a variety of systems, serving as a basis for fair comparisons of the extent of dynamical heterogeneity and has become a central tool in characterizing dynamic heterogeneity in amorphous materials [18].

FIG. 3: Spatial map of single particle displacements in the simulation of a Lennard-Jones model of a supercooled liquid in two spatial dimensions. Arrows represent the displacement of each individual particle in a trajectory of duration comparable to the typical structural relaxation time. This map reveals that particles with different mobilities are spatially correlated.
For each temperature, $\chi_4(t)$ has a maximum, which shifts to larger times and has a larger value when $T$ is decreased, revealing the increasing length scale of dynamic heterogeneity in supercooled liquids that approach the glass transition.

The dynamical function $\chi_4(t)$ has now been measured in computer simulations of many different glass-forming liquids, by molecular dynamics, Brownian, and Monte Carlo simulations. An example is shown in Fig. 4 for a Lennard-Jones numerical model, but the qualitative behavior is similar in all cases: as a function of time $\chi_4(t)$ increases at first, it has a peak on a timescale of the order of the typical relaxation time of the fluid, and then it decreases at large times. This time dependence simply reflects the transient nature of the dynamical heterogeneity.

The peak value of $\chi_4(t)$ approximately measures the volume over which structural relaxation processes are correlated. Therefore, the most important result obtained from data such as those presented in Fig. 4 is the temperature evolution of the peak height, which is found to increase when the temperature decreases and the global dynamics slows down. Such data provides direct evidence that the approach to the glass transition is accompanied by the development of increasingly long-ranged spatial correlations of the dynamics.

In experiments, direct measurements of $\chi_4(t)$ have been made in colloidal and granular materials close to the colloidal and granular glass transitions, and also in foams and gels, because dynamics is more easily spatially and temporally resolved in those cases. The results obtained in all these cases are again broadly similar to those shown in Fig. 4 both for the time dependence of $\chi_4(t)$ and its evolution with a change of the relevant variable controlling the dynamics.

Obtaining information on the behavior of $\chi_4(t)$ and $G_4(r; t)$ from experiments on molecular systems is difficult, because it is hard to disentangle the spontaneous fluctuations embodied in $\chi_4(t)$ in Eq. (4) from the experimental noise. Such measurements are however crucial because numerical simulations and experiments on colloidal and granular systems can typically only be performed for relaxation times spanning at most 5-6 decades. On the other hand, in molecular liquids, up to 14 decades are in principle relevant, and extrapolation of simulation data all the way to the experimental glass transition is fraught with difficulty. Indirect estimates of $\chi_4(t)$ from experiments are discussed below.

**REAL-SPACE MEASUREMENTS AND DYNAMIC STRUCTURE FACTORS**

We mentioned above that a growing peak in $\chi_4(t)$ “directly” reveals the growth of a dynamic correlation length scale as the glass transition is approached. This can only be true if the assumptions made in Eq. (3) for the scaling form of $G_4(r; t)$ are correct. Dynamic length scales should in principle be obtained by direct measurements of a spatial correlation function.

However, in contrast to $\chi_4(t)$, detailed measurements of $G_4(r; t)$ are technically more challenging as dynamic correlations must now be resolved in space over a large range of distances with a very high precision, and so there is much less data to draw on. From the point of view of numerical simulations where many measurements of $\chi_4$ were reported, the main limitation to properly measuring $\xi_4$ is the system size. This might seem surprising as typical numbers extracted for the correlation length scale $\xi_4$ are rather modest, but a precise determination of $\xi_4$ requires an accurate study of the tail of $G_4(r; t)$ at large $r$, which entails an important numerical effort.

However, such studies are important in that they allow the dynamical length scale $\xi_4(t)$ to be measured directly. Moreover, such studies help infer the behavior of $\xi_4(t)$ from measurements of $\chi_4(t)$. Published work is consistent with $\chi_4(t)/G_4(0, t)$ representing the number of particles involved in heterogeneous relaxation. Therefore, truly ‘direct’ measurements indeed confirm that the increase of the peak of $\chi_4(t)$ corresponds, as expected, to a growing dynamic length scale $\xi_4(t)$.

Instead of direct inspection of $G_4(r; t)$, it is often convenient to analyse its Fourier transform,

$$S_4(q; t) = \int d^d r e^{i qr} G_4(r; t).$$

which is known as the four-point structure factor of dynamic heterogeneity. In Fourier space, the large domains observed in Fig. 3 impact the low wavevector behavior of $S_4(q; t)$ in the form of a peak that grows when the glass transition is approached. This peak is often fitted with...
the Ornstein-Zernike functional form which is frequently used in conventional critical phenomena [3].

**EXPERIMENTAL ESTIMATES OF MULTIPUNCT SUSCEPTIBILITIES**

Although readily accessible in numerical simulations, the fluctuations that give access to $\chi_4(t)$ are in general very small and impossible to measure directly in experiments, except when the range of the dynamic correlation is macroscopic, as in granular materials [14] or in soft glassy materials where it can reach the micrometer and even millimetre range [28, 29, 32]. To access $\chi_4(t)$ in molecular liquids, one should perform time-resolved dynamic measurements probing very small volumes, with a linear size of the order of a few nanometers.

Fortunately, simpler alternative procedures exist. The central idea underpinning these solutions is the realisation that if it is generally hard to detect noise in an experiment, it is usually simpler to measure the response of a system to an external perturbation. In the linear response regime, both types of measurements can often be related to one another by fluctuation-dissipation theorems [3]. The physical motivation is that while four-point correlations offer a direct probe of the dynamic heterogeneities, other multi-point correlation functions might also give useful information about the microscopic mechanisms leading to these heterogeneities.

For example, one might expect that a local fluctuation of the enthalpy $\delta h_x(t = 0)$ at position $x$ and time $t = 0$ triggers or eases the dynamics in its surroundings, leading to a systematic correlation between $\delta h_x(t = 0)$ and $c(x + r; t, 0)$. A similar effect is expected for a local fluctuation of the density. These physical intuitions suggest the definition of a family of three-point correlation functions that relate thermodynamic fluctuations at one point to dynamical ones at another point. Crucially, some of these three-point correlations are both experimentally accessible and give bounds or approximations to the four-point dynamic correlations [33].

Based on this insight, one may obtain a lower bound on $\chi_4(t)$ by using a fluctuation-dissipation relation, which is valid at equilibrium when the energy is conserved by the dynamics [33]:

$$\chi_4(t) \geq \frac{k_B T^2}{c_P} [\chi_T(t)]^2,$$

where $\chi_T(t)$ quantifies the *response* of the average mobility to an infinitesimal change in the temperature $T$, and $c_P$ is the specific heat per particle. The response $\chi_T(t)$ can be experimentally accessed by measuring the average of a dynamical correlator, $\langle C(t, 0) \rangle_T$, at nearby temperatures, $T$ and $T + \delta T$, in the linear regime $\delta T \ll T$:

$$\chi_T(t) \approx \frac{\langle C(t, 0) \rangle_{T+\delta T} - \langle C(t, 0) \rangle_T}{\delta T}.$$

The main experimental advantage of [33] is that spatiotemporal resolution is not needed, contrary to Eq. (3).

Detailed numerical simulations and theoretical arguments [29] strongly suggest that the right hand side of Eq. (4) actually provides a good estimate of $\chi_4(t)$ in supercooled liquids, and not just a lower bound. Similar estimates exist considering density instead of the temperature in Eq. (3). These are useful when considering colloidal or granular materials where the glass transition is mostly controlled by the packing fraction. The quality of the corresponding lower bound was tested experimentally on granular packings close to the jamming transition [34], and numerically for colloidal hard spheres [30, 31].

We show in Fig. 5 a compilation of data [36] for the evolution of the peak height of $\chi_4$, in a representation inspired by the theory of dynamic critical phenomena [3]. These data represent an experimental confirmation that dynamic fluctuations and correlation length scales grow appreciably when molecular liquids approach the glass transition. However, we also learn that typical length scales do not become very large (remaining in the nanometer scale for molecular glass-formers) before liquids vitrify in a nonergodic state, and that an "ideal" glass critical point is not readily accessible to experiments.
THEORETICAL DEVELOPMENTS

The above results are also relevant because many theories of the glass transition have assumed or predicted that the dynamics slows down because there are increasingly large regions over which particles have to relax in a correlated manner. However, in the absence of experimental signs of growing length scales, these theoretical constructions would have remained speculative.

The measurements of the spatial extent of dynamic heterogeneity, in particular $\chi_4(t)$ and $G_4(r; t)$, seem to provide the long-sought evidence that the glass transition must indeed be considered as a form of critical or collective phenomenon involving growing timescales and length scales. This is important for the field of glass transition, even though a conclusive understanding of the relationship between dynamical length scales and relaxation timescales is still the focus of intense research.

From a theoretical perspective, we are familiar with the idea, borrowed from equilibrium critical phenomena, that when correlation length scales get large, microscopic features of the system become unimportant and “universal” behaviors emerge. Whether realistic glassy systems have length scales that are large enough for such a universal description remains unclear. Although most theoretical approaches are in this spirit, one should perform an equally careful treatment of pre-asymptotic effects, which obviously matter for experiments that are performed far away from (putative) criticality. Therefore, theories of the glass transition are still crude descriptions of reality, despite large research efforts.

Distinct microscopic mechanisms have been proposed that all give rise to growing dynamic correlations similar to the ones revealed by four-point functions. This relative abundance of approaches can be interpreted in two ways. A first view is to consider dynamic heterogeneity as a unifying physical phenomenon that accompanies the formation of glasses, and is central to its theoretical understanding. The second, more pessimistic interpretation, is that if any reasonable theory predicts increasingly spatially heterogeneous dynamics, then studying dynamic heterogeneity might not help make substantial theoretical progress. This argument is balanced by the fact that the mere observation of dynamic heterogeneity has forced theoreticians to work hard on many fronts to understand what sort of microscopic mechanism is able (or not) to provide for instance new insights or quantitative predictions for the behavior of multipoint correlation functions, susceptibilities and dynamic correlation length scales.

Several theoretical schemes, such as mode-coupling theory, the random first-order transition theory, dynamic facilitation approach, and frustration-limited domain scaling picture have now been developed to the point that they provide useful theoretical guides to understand and analyze various aspects of dynamic heterogeneity, see 2 for a general theoretical review. One can thus hope that these approaches contain useful seeds for the construction of a “unified” theory of the glassy state. In all of these approaches, dynamic heterogeneity and spatio-temporal fluctuations feature as central concepts.

PERSPECTIVES

Although we mostly discussed supercooled liquids near the molecular glass transition, we must emphasize that other materials have played an important role in developing the concepts and tools described above. For instance, several soft condensed materials such as colloidal assemblies have been instrumental in understanding the phenomenon of dynamic heterogeneity, because they share important similarities with molecular liquids but their elementary constituents are so much larger than atoms (in the range 50 nm – 1μm) that they can more easily be visualized. Driven granular media (sheared or agitated systems) also undergo a “granular” glass transition which is empirically similar to the molecular transition. In that case, grains can even be directly tracked using a standard camera. These studies have contributed to give flesh to the concept of dynamic heterogeneity, because spatial fluctuations could be seen.

In the introduction we alluded to the rigidity transition occurring in athermal disordered granular packings. This “jamming” transition arises in an assembly of rigid particles when the system cannot be compressed anymore, and is thus mainly a geometric transition where thermal fluctuations play no role. For spherical particles of equal sizes, this transition occurs near ‘random close packing’ $\varphi_{rcp} \approx 0.64$. The jamming transition is relevant also for athermal assemblies of soft particles, such as foams and emulsions, which are thus additional examples of disordered rigid materials. Connections with the physics of glasses are still rather speculative but are currently the focus on an important research effort. Detailed studies of dynamic heterogeneity in packings of soft and hard particles near random close packing started to appear only recently, and could help elucidating similarities and differences between glasses and granular materials.

One of the most frequently asked questions in studies of dynamical heterogeneity is whether the observed dynamic fluctuations and correlations might have a structural origin: Is there, after all, a “hidden” thermodynamic order parameter which would exhibit spatial fluctuations comparable to the ones revealed by dynamic heterogeneity studies? This question has attracted sustained interest. For example, in very early numerical work on dynamic heterogeneity, immobile regions were discussed in connection with compositional fluctuations in fluid mixtures. However, dynamic heterogeneity...
would not have emerged as an important concept if a simple, direct connection between structural order and relaxation dynamics had been satisfactorily established in amorphous materials. In that case, research would be dedicated to understanding the development of structural correlations at low temperatures in supercooled liquids, and to developing tools to measure, quantify and analyse such static features. Having said this, recent research on isoconfigurational ensembles \cite{12}, amorphous order \cite{13} and point-to-set correlations \cite{14}, suggests that the structure of disordered materials might well be the next topic where new discoveries and concepts will emerge in the near future. While two-point static correlations are poorly correlated to the local structure of simple, direct connection between structural order and physical properties.
