ABSTRACT
A search for matched circle pairs of similar temperature fluctuations in the final Wilkinson Microwave Anisotropy Probe (WMAP) 9 yr data is carried out. Such a signature is expected if the space of the Universe is multiply connected. We investigate the relation between the pixel resolution of cosmic microwave background (CMB) maps and a Gaussian smoothing in order to lower the probability for missing matched circle pairs. CMB maps having the 3-torus topology are generated with the characteristics of the WMAP satellite in order to determine how large the smoothing should be chosen in CMB maps disturbed by detector noise. The V- and W-band data are analysed with respect to matched circle pairs and a tentatively signal is found for a circle pair, which lies, however, close to the plane of the Galaxy. It is, however, inconclusive whether this signal is generated by chance, is due to residual foregrounds contained in the V- and W-band maps, or is due to a genuine topology.

Key words: cosmic background radiation – large-scale structure of Universe.

1 INTRODUCTION
Since the cosmic microwave background (CMB) radiation provides us with the earliest admissible electromagnetic radiation, it contains information about the largest scales of our Universe. Therefore, it is most promising to search for topological signatures in the CMB radiation in order to reveal the topology of our Universe. One of the topological tests is the matched circle test proposed by Cornish, Spergel & Starkman (1998) on which this paper puts its focus. For an introduction into the topic of cosmic topology and discussions concerning topological tests, see Lachièze-Rey & Luminet (1995), Luminet & Roukema (1999), Levin (2002), Reboucas & Gomero (2004), Luminet (2008), Mota et al. (2010, 2011) and Fuji & Yoshii (2011).

The idea behind this test is the following. The CMB sky observed from a given observer position originates from a sphere around this observer, i.e. from the surface of last scattering (SLS). If the Universe possesses a non-trivial topology, the space can be viewed as being tessellated by cells which have to be identified. This space is the so-called universal cover. Each cell has a ‘clone’ of the observer, which observes the same CMB sky. If the observer and a given clone are not farther separated than the diameter of the SLS, the two spheres overlap in the universal cover. The intersection of the two spheres is a circle seen by the observer and its clone in a different direction. Since the observer and its clone are to be identified, one concludes that two circles should exist on the CMB sky with identical temperature fluctuations seen in different directions but with the same radius. A non-trivial topology is thus betrayed by as much pairs of circles with the same temperature fluctuations as there are clones of the observer not farther away than the diameter of the SLS.

This description is simplified since it ignores several effects which alter the CMB temperature fluctuations of the observer and its clone in a different way, so that the temperature fluctuations on both circles are no longer identical. The two most important CMB contributions in this respect are the Doppler contribution, whose magnitude depends on the velocity projection towards the observer, and the integrated Sachs–Wolfe (ISW) contribution, which arises along the path from the SLS to the observer or to the clone. These two paths are not identified and lead to different contributions to the total CMB signal. These issues are discussed in more detail by Aurich, Lustig & Steiner (2006), Riazuelo et al. (2006), Key et al. (2007) and Bielewicz & Banday (2011). There are further degrading effects, e.g. the finite thickness of the SLS, but these are considered as subdominant to the Doppler and ISW contribution. Despite these degrading effects, there should be a detectable topological signal.

In addition to these contributions, which can be computed with the standard CMB physics, there are residuals left over by the subtraction of foreground sources which have their own uncertainties.

The circles-in-the-sky (CITS) test requires a full sky survey and has been applied to different sky maps derived from the Cosmic Background Explorer (COBE) and Wilkinson Microwave Anisotropy Probe (WMAP) missions. Roukema (2000a,b) applied the CITS test to the COBE data. Cornish et al. (2004) and Key et al. (2007) analyse the first year CMB data with respect to nearly back-to-back circle pairs with a negative result. A hint of the Poincaré dodecahedral topology is found by Roukema et al. (2004) in the first year data. The circle signals correspond to circles with a small radius of about 11°. This claim could not be confirmed by Key et al.
The analysis of Aurich et al. (2006) uses a weight function constructed to suppress the Doppler and ISW contributions. It does not find a convincing signal, and only a marginal hint is found in favour of the Poincaré dodecahedral space. The three-year WMAP data are investigated with respect to the 3-torus topology by Aurich et al. (2008), and it is found that the degree of uncertainties in the CMB map must be significantly below 50 μK in order to have a realistic chance to discover such a topology. The seven-year WMAP data are analysed by Bielewicz & Banday (2011) with respect to back-to-back circle pairs. They rule out topologies having such circle pairs with radii larger than 10°. This work emphasises the presence of residual Galactic foreground emission close to the Galactic plane in the WMAP Internal Linear Combination (ILC) 7 yr map and chooses to use a mask to eliminate this non-CMB contribution. The search for general circle pairs that are not back to back is carried out by Vaudrevange et al. (2012). Although some signals are detected, they are ascribed to the residual foreground contained in the ILC map which is used within the WMAP Kp12 sky mask. This analysis concludes that no topological signal is present in the seven-year WMAP data with circle radii above 10°. A CITS search for an orbifold line topology is carried out by Rathaus, Ben-David & Itzhaki (2013) and a tentative candidate match is found.

Are those topological spaces definitely ruled out by these CMB analyses? In order to exclude or find possible loop holes in the matched circle pair signal, we generate a high-resolution CMB sky map for the 3-torus topology which requires a space with zero curvature, i.e., an Euclidean space. This map is analysed with respect to the amplitude of the topological signal.

The 3-torus map is computed using the cosmological parameters of the ΛCDM concordance model which are published by Jarosik et al. (2011) in their table 8, column ‘WMAP+BAO+H0’ (Q_{bua} = 0.0456, Q_{bim} = 0.227, Hubble constant h = 0.704, reionization optical depth τ = 0.087, scalar spectral index n_s = 0.963). In the following, only the cubic 3-torus is considered where all three topological lengths have the same value L. In units of the Hubble length L_q = c/H_0, the chosen side length is L = 1.5 in Sections 2–4. This value is significantly smaller than that obtained from the requirement that the CMB temperature correlations of the model should match the observed correlations. A best fit of the correlations leads to values around L = 4, see fig. 11 in Aurich & Lustig (2011). It should be noted that this 3-torus topology with L = 4 could be detected in future high-redshift galaxy surveys as emphasized by Roukema et al. (2013) which would be independent of the CMB analyses. The reason for the unrealistically small value of L = 1.5 is that the CMB anisotropies have to be computed by using the eigenmodes of the 3-torus, and we want to accurately compute the CMB map up to the multipole moment C_L with l_{max} = 3000. To achieve this fine structure for the chosen cosmological parameters, all eigenmodes with a wavenumber k up to k = 1026 are included. This means that 61 556 892 different wavenumbers k are taken into account. The simulation of a CMB map for L = 4 with that resolution is currently not feasible. However, the amplitude of the signal due to a single pair of matched circles should be independent of the size of the fundamental cell. The size determines, however, the number of matched circle pairs which decreases with increasing size of the 3-torus cell. The cubic 3-torus topology with L = 4 possesses six circle pairs with radius α ≃ 31° and three circle pairs with radius α ≃ 53°. The total number of circle pairs increases to 182 for L = 1.5. Thus, the simulation with L = 1.5 has the advantage that there are much more circle pairs to analyse with respect to their discovery probability. For the decision, whether a cell with L = 4 is discovered with certainty, one has to take the much smaller number of circle pairs into account. The CMB sky map for the 3-torus with L = 1.5 is generated in the Hierarchical Equal Area isoLatitude Pixelization (HEALPix) format (Górski et al. 2005) with a resolution of N_{side} = 4096. This map possesses a pixel size of 51.5 arcsec which is three times smaller than the resolution of the simulation being of the order of 180°/l_{max} ≃ 3.6 arcmin. The following analysis is mainly based on this map. We will also use less accurate L = 4 simulations in Sections 5 and 6 when the detector noise is taken into account since in that case a lower accuracy of the simulation is sufficient. Furthermore, we restrict us to a search of back-to-back circle pairs.

2 THE CITS AMPLITUDE FOR INDIVIDUAL CIRCLE PAIRS

Let us now turn to the correlation measure used for the detection of CITS signals. The expansion of the temperature δT_i(φ) along a circle in a Fourier series δT_i(φ) = \sum \delta T_{im} e^{imφ}, 0 \leq φ \leq 2\pi, allows one to define the m-weighted circle signature for two circles i and j having a radius α as (Cornish et al. 2004)

\[ S_{ij}(α, β) := \frac{2}{\sum_m m \delta T_{im} \delta T_{jm} e^{imβ}} \left( \frac{1}{|\delta T_{im}|^2 + |\delta T_{jm}|^2} \right). \]

The angle β takes a possible shift between the two circles into account. A perfect correlation would be revealed by S_0(α, β) = 1, but due to the degrading Doppler and ISW contributions, the actual value is lower. Then the maximum is taken over all circle pairs and all shift angles β for a fixed circle radius α, i.e.

\[ S(α) = \max_{i,j,β} S_{ij}(α, β). \]

In the following we restrict this analysis to back-to-back circles which determines the index j as a function of i. Every pixel i of the HEALPix map is treated as a possible centre of a circle in the CITS search.

Even if the correlation S(α) is computed for a CMB map belonging to a model with a simply connected topology, one obtains non-vanishing correlations by chance. The smaller the rings, the higher is the probability that the temperature fluctuations are accidentally correlated. This leads to a background for S(α), which starts at S(α) ≃ 1 for α = 0 and declines towards larger radii α until at α = 90° the pairs are mapped on to each other leading again to S(α) ≃ 1. A topology can only be discerned if the CITS correlation due to a matched circle pair is significantly larger than this background.

This background behaviour is shown in Fig. 1, where the CITS correlation S(α) is computed from a 3-torus simulation with L = 1.5 as described in the introduction. The dotted curve belongs to S(α) obtained as the maximum taken over all occurring back-to-back circle pairs and all shifts β. Even for very large radii α, the background is not far below 0.3. Since there are 182 matched circle pairs, every peak in S(α) is generated by the circle pair with the highest signal. The figure also reveals the variation in the CITS signal for the individual pairs. For each pair, the individual CITS value is depicted by a small circle in Fig. 1. For α < 20° the CITS values of matched circle pairs are below the background of non-matched circle pairs, so that such small matched circle pairs can probably not be detected. Above α ≃ 25° the matched circle pairs can be detected under the optimal conditions assumed here, where a pure CMB map without foregrounds and detector noise is available.

Fig. 1 also shows the CITS correlation S(α) obtained from the subset of circle pairs having all the same circle centres. For such a subset, the background due to non-matched circle pairs is much
CMB signal. Even without noise a smoothing can be advantageous. Since the data are given on a discretized map, the scan strategy can miss the very localized peaks if the search grid is too coarse. If the data are sufficiently smoothed, even a relatively coarse search grid can find the topological signal, and a lot of computer time can be saved. However, a too strong smoothing will eliminate the CITS signal. Thus, there is a relation of how strong the smoothing should be for a given HEALPix resolution $N_{\text{side}}$. As discussed in the introduction, the CMB signal is composed of different contributions and only the Sachs–Wolfe contribution leads to a clear CITS signal while the Doppler and ISW contributions deteriorate it. The Sachs–Wolfe contribution provides the largest signal on scales around the first acoustic peak having a scale of roughly 0.8. Thus, the smoothing should at least be smaller than that in order to preserve the information due to the Sachs–Wolfe contribution.

We use a Gaussian smoothing which multiplies the expansion coefficients $a_{lm}$ of the temperature fluctuations $\delta T(\hat{\theta})$ with respect to spherical harmonics $Y_{lm}(\hat{\theta})$ by

$$a_{lm}^\text{sm} = a_{lm} e^{-\frac{l(l+1)\theta^2}{2\sigma^2}} \quad \text{with} \quad \sigma = \frac{\pi}{2\sqrt{2}\log 2}.$$  

where $\theta$ is the smoothing in degrees.

This Gaussian smoothing is applied to the 3-torus simulation with $L = 1.5$. The simulated CMB map is smoothed using the map in the HEALPix resolution $N_{\text{side}} = 4096$. After the Gaussian smoothing, the map is downgraded to $N_{\text{side}} = 256$, and the CITS correlation $S(\alpha)$ is calculated using this $N_{\text{side}} = 256$ map. The result is shown in Fig. 2, where the smoothing parameters $\theta = 0.1, 0.4$ and 0.6 are used. Panel (a) displays the correlation obtained from the $\theta = 0.1$ and 0.4 maps. The background of $S(\alpha)$ increases by increasing the smoothing parameter $\theta$, but, on the other hand, also the CITS signal of the matched circle pair increases. In order to decide whether there is an improvement by increasing $\theta$ from $\theta = 0.1$ to 0.4, the figure also shows the difference $S_{\theta=0.4}(\alpha) - S_{\theta=0.1}(\alpha)$ as a dashed curve. The difference curve reveals the increasing background but also that the peaks are more pronounced for $\theta = 0.4$, since the peaks are higher than the background. Thus, the height of the CITS peaks increases more than the background. Increasing the smoothing further to $\theta = 0.6$ does not lead to an improvement as shown in panel (b). In panel (b) the difference curve $S_{\theta=0.6}(\alpha) - S_{\theta=0.4}(\alpha)$ shows for ring radii $\alpha \lesssim 50^\circ$ dips towards negative values. Thus, the increase of the background is larger than the gain in the peak heights. Even for very large rings there is no genuine gain in the height of the peaks, but, instead, they are only extended towards smaller values of $\alpha$. The focus of the smoothing should be put on the improvement of the signal for medium rings. Therefore, the smoothing parameter $\theta$ should be smaller than 0.6. We have investigated other smoothing parameters $\theta$ in this way and conclude that for $N_{\text{side}} = 256$, the best smoothing parameter is about $\theta = 0.4$.

Let us now address the best choice of the smoothing parameter $\theta$ for the HEALPix resolution $N_{\text{side}} = 512$. To that aim, the simulated CMB map is again smoothed using the map in the HEALPix resolution $N_{\text{side}} = 4096$. But after the Gaussian smoothing, the map is only downgraded to $N_{\text{side}} = 512$. The CITS correlation $S(\alpha)$ is calculated from this $N_{\text{side}} = 512$ map and shown in Fig. 3 in the same way as Fig. 2 displays the $N_{\text{side}} = 256$ results. Panel (a) shows the increase in the background by increasing the smoothing from $\theta = 0.1$ to 0.4, but at least for $\alpha \gtrsim 40^\circ$ the difference curve reveals an improved signal. However, for smaller ring radii the result is inconclusive since positive as well as negative deviations from the background are observed. This suggests a twofold search if one insists on the $N_{\text{side}} = 512$ resolution: choosing $\theta = 0.4$ for larger

#### 3 SMOOTHING AND THE CITS AMPLITUDE

Let us now turn to the important question how the smoothing of a CMB map can improve the amplitude of a CITS signal of a matched circle pair so that its peak emerges out of the background. This can be essential for detecting a possible topology. There are several reasons why a smoothing of the map should be carried out. On the one hand, the temperature values of the pixels contain not only the pure CMB signal, but in addition the noise of the detector. Assuming that the noise is independent from pixel to pixel, a smoothing suppresses the noise contribution leading to a cleaner

---

**Figure 1.** The CITS correlation $S(\alpha)$ is calculated for a 3-torus simulation with $L = 1.5$ using the HEALPix resolution $N_{\text{side}} = 512$ and a Gaussian smoothing with $\theta = 0.5$. The dotted curve shows $S(\alpha)$ obtained from all back-to-back circle pairs and all shift angles $\beta$. The open circles reveal the CITS values obtained from the 182 matched circle pairs of this topology. The dashed, full and dot–dashed curves belong to the subset of circle pairs having the same circle centres as one of the matched circle pairs with radii $\alpha = 20.5, 24.7$ and 56.2, respectively. The CITS values of these matched circle pairs are depicted by red dots.
Figure 2. The CITS correlation $S(\alpha)$ is calculated for a 3-torus simulation with $L = 1.5$ using the HEALPix resolution $N_{\text{side}} = 256$ and three different Gaussian smoothing. Panel (a) compares the CITS correlation for the two smoothing parameters $\theta = 0.1^\circ$ and $0.4^\circ$, while panel (b) compares $\theta = 0.4^\circ$ and $0.6^\circ$. The dashed curve, which starts for $\alpha = 0$ at zero, displays the difference between the two CITS correlations $S(\alpha)$ shown in the panel.

Figure 3. The CITS correlation $S(\alpha)$ is shown for the same simulation as in Fig. 2 but now calculated from the map in the HEALPix resolution $N_{\text{side}} = 512$. Panel (a) compares the CITS correlation for the two smoothing parameters $\theta = 0.1^\circ$ and $0.4^\circ$, while panel (b) compares $\theta = 0.4^\circ$ and $0.6^\circ$. The dashed curve, which starts for $\alpha = 0$ at zero, displays the difference between the two CITS correlations $S(\alpha)$ shown in the panel.

4 THE SEARCH GRID

In the CITS search, every pixel of the HEALPix map is considered as a possible circle centre of a matched circle pair. The $N_{\text{side}}$ resolution leads to $12N_{\text{side}}^2$ pixels and determines how thoroughly the circles are scanned. However, it is not necessary to use for the circle centres, for which the CITS amplitude is to be computed, the same resolution as for the CMB map. Vaudrevange et al. (2012) carry out their CITS search on a CMB map having the resolution $N_{\text{side}} = 512$, but for the circle centres they use the coordinates of the pixel centres of the HEALPix map with the resolution $N_{\text{grid}} = 128$. This procedure saves a lot of computer time since the number of circle centres is reduced by a factor of 16. Except in this section, we always use the same resolution for the search grid and the CMB map.

The coarser search grid harbours the risk that some matched circle pairs get missed. In order to test this issue, we calculate the CITS correlation $S(\alpha)$ from our 3-torus simulation with the HEALPix resolution $N_{\text{side}} = 512$ and a Gaussian smoothing $\theta = 0.4^\circ$. In the first case, we use $N_{\text{grid}} = 512$ and search all pixel centres of the $N_{\text{side}} = 512$ map, and in the second case only those of the $N_{\text{grid}} = 128$ mesh. The result can be inferred from Fig. 4, where the dotted curve shows the $N_{\text{grid}} = 512$ search and the full curve uses the
sparse $N_{\text{grid}} = 128$ grid. Several smaller rings are found only on the $N_{\text{grid}} = 512$ grid, see $\alpha = 24.7$ in Fig. 4. The CITS correlations for the rings with radii $\alpha = 31.8$ and 50.0 are reduced by a factor of 2. Taking into account that our map contains the clean CMB signal without noise and residual foregrounds, it seems that also these signatures can be overlooked. Furthermore, if the multiply connected space has significantly fewer matched circle pairs as it is the case for the $L = 4$ torus topology (six at $\alpha \simeq 31^\circ$ and three at $\alpha \simeq 53^\circ$) mentioned in the introduction, even this back-to-back signature can be missed. To emphasize the large number of matched circle pairs in the $L = 1.5$ case, Fig. 4 also displays the CITS values at the pixel centres that provide the best match to the circle centres as small discs ($N_{\text{grid}} = 512$) and open squares ($N_{\text{grid}} = 128$). It is obvious that a lot of matched circle pairs for the $N_{\text{grid}} = 128$ search are below the background even for $\alpha \lesssim 50^\circ$. All the open squares below the background level would never be considered as candidates for a possible refined search. Furthermore, since the CITS search of Vaudevange et al. (2012) refers to non-back-to-back circle pairs, their background level is higher than in our back-to-back search. This worsens the situation, so that we doubt that their analysis excludes such matched circle pairs.

Although the computer time would rise dramatically, one could ask how a search grid, which is finer than the resolution of the CMB map, would improve the CITS signature. To address this point, the CITS correlation $S(\alpha)$ is computed for two search grids with $N_{\text{grid}} = 512$ and 1024 on the 3-torus simulation with the HEALPix resolution $N_{\text{side}} = 512$ and a Gaussian smoothing $\theta = 0.2$. As Fig. 5 reveals that the improvement justifies the increase in computer time only for small rings with radii $\alpha = 20^\circ - 30^\circ$, where the stronger CITS signal is crucial. A similar comparison is carried out for an $N_{\text{side}} = 256$ CMB map, where two search grids with $N_{\text{grid}} = 256$ and $N_{\text{grid}} = 512$ are used. It turns out that only for smoothing parameters which are so small that the pixelization determines the resolution of the CMB map, an oversampling with $N_{\text{grid}} > N_{\text{side}}$ leads to significantly better results especially for ring radii in the range $\alpha = 20^\circ - 30^\circ$.

\section*{5 NOISE AND THE CITS AMPLITUDE}

In the previous sections, the CITS signature is analysed only for CMB map simulations which contain the pure CMB signal. Only deteriorating effects that have their origin in the CMB physics such as the Doppler and the ISW effect were taken into account. The experiments, in contrast, yield CMB maps which are perturbed by noise and the beam profile of the detector.

In order to address that issue, the 3-torus CMB map is modified according to the beam profile $b_{V1, W1}(l)$ of the W1 and V1 channels (Bennett et al. 2012) as given on the Legacy Archive for Microwave Background Data Analysis (LAMBDATA) website using the HEALPix resolution $N_{\text{side}} = 4096$. Thereafter, a downgrade from $N_{\text{side}} = 4096$ to 512 is carried out. In the next step, the noise of the pixel $i$ is computed from the number $N_{\text{det}}(i)$ of observations of the pixel $i$ as a Gaussian random error with standard deviation $\sigma_0 / \sqrt{N_{\text{det}}(i)}$ and added to the map in the $N_{\text{side}} = 512$ resolution. This map is expanded with respect to $a_{\text{lim}}$ and the Gaussian smoothing is realized as

$$a_{\text{lim}}^{\text{sm}} = a_{\text{lim}} e^{-\frac{\mu_{l, \text{lim}}^2}{2}} / b_{V1, W1}(l),$$

so that the final smoothing is independent of the non-Gaussian beam profile $b(l)$. This sequence of operations leads to CMB maps for the 3-torus topology comparable to the quality of the corresponding WMAP 9 yr observations in the $V$ and $W$ bands.

In this section, CMB maps for the 3-torus with side length $L = 4.0$ are analysed. In contrast to the $L = 1.5$ simulation, only multipoles $l$ with $l \leq 1000$ are included in the $L = 4.0$ case. This simulation is accurate enough for an analysis with respect to noise as can be inferred from Fig. 6. For $l > 1000$, the angular power spectrum $\delta T_{l}^2$ is noise dominated for the $V$ and $W$ bands of the WMAP measurements which are put into focus in this section. The comparison of the two panels of Fig. 6 shows that the $W$ band has a higher noise.
contribution than the V band, although the W-band beam profile reveals tentatively the third acoustic peak by ignoring the noise.

It is interesting to evaluate the CMB maps, which are processed to mimic the V- and W-band maps of WMAP, in the $N_{\text{side}} = 512$ resolution without further smoothing. Fig. 7 shows that the CITS signature of the six ring pairs at $\alpha = 31:1$ is missing at the $N_{\text{side}} = 512$ resolution in both bands. Only the three ring pairs at $\alpha = 52:7$ emerge slightly from the background, where the signature is more pronounced in the V band having less noise. The CITS signature is swamped by the noise as a simple downgrade to the $N_{\text{side}} = 256$ resolution reveals. Here the average over 4 pixels yields the temperature value in the $N_{\text{side}} = 256$ resolution. The improvement can be seen by the dotted curves in Fig. 7. Despite the increased background, the CITS signature is visible more clearly. This demonstrates that the V- and W-band CMB maps have to be smoothed in order to reduce the degrading effects due to noise.

The importance of the smoothing to reduce the noise is also revealed by the following analysis. At first the CMB map with the V-band properties in the $N_{\text{side}} = 512$ resolution, whose CITS correlation is shown in Fig. 7(a), is smoothed according to equation (4). This smoothing is done in the $N_{\text{side}} = 512$ resolution for various values of $\theta$. The optimum is found in the range between $\theta = 0.4$ and 0.5. For smoothing parameters $\theta$ below $\theta = 0.4$ the noise degrades the CITS signal and above $\theta = 0.5$, the smoothing removes too much CMB information. The CITS correlation is plotted in Fig. 8(a) for $\theta = 0.4$ and 0.5, and the improvement compared to Fig. 7(a) (full curve) is obvious. In addition, the difference curve is plotted which shows that both smoothing parameters lead to nearly indistinguishable results. In panel (b) of Fig. 8 the analogous curves are shown for the CMB map which is downgraded to the $N_{\text{side}} = 256$ resolution. Since the computer time is reduced for the smaller
The circles-in-the-sky test

Figure 8. The CITS correlation $S(\alpha)$ is calculated for the 3-torus simulation with $L = 4.0$ using the beam profile and the detector noise of the $V$ band. The CMB map is smoothed using the parameters $\theta = 0^\circ.4$ and $0^\circ.5$. In panel (a), $S(\alpha)$ is obtained from the $N_{\text{side}} = 512$ CMB map, while panel (b) shows the corresponding curves obtained from the $N_{\text{side}} = 256$ CMB map. The difference curve is also shown.

$N_{\text{side}} = 256$ resolution, we will use in the following this value of $N_{\text{side}}$.

Up to now the analysis is based on a single CMB simulation for the 3-torus topology either for $L = 1.5$ or for $L = 4.0$. However, the CMB simulations require Gaussian random initial conditions leading to a statistical ensemble of CMB simulations belonging to a given topology of a fixed side length $L$. In order to address the question how this variability affects the CITS signature, an ensemble of 100 CMB simulations for the 3-torus with $L = 4.0$ is generated. This leads to 100 CMB maps where the beam profile $b_{V}(l)$ and the detector noise of the $V$ band is taken into account as described above. The results for the two smoothing parameters $\theta = 0.4$ and $0.5$ are presented in Fig. 9. The dotted curve shows the largest CITS signature that occurs in the 100 simulations, while the full curve shows the worst case that is the minimum over the 100 CITS correlations $S(\alpha)$. Individual matched circle pairs can possess even lower values, but note that $S(\alpha)$ takes the maximum of the six pairs at $\alpha = 31.1$ and of the three pairs at $\alpha = 52.7$. A detailed analysis reveals that the smoothing parameter $\theta = 0.5$ yields marginally better peaks than the choice $\theta = 0.4$.

At radii $\alpha$ where no matched circle pair is nearby, the correlations $S_{ij}(\alpha, \beta)$, see equation (1), show (positive) correlations and (negative) anticorrelations with the same amplitude, so that the minimum of the anticorrelations, defined by

$$S_{bg}(\alpha) = \max_{i,j,\beta} (-S_{ij}(\alpha, \beta)), \quad (5)$$

is a measure of the background even at radii $\alpha$ where matched circle pairs do occur. Thus, it quantifies the detection threshold. Fig. 9 shows the distribution of $S_{bg}(\alpha)$ obtained from the 100 simulations as the shaded band. This distribution is asymmetric with a tail towards larger values, and Fig. 9 also shows as the grey band the band which contains 66 per cent of the values of $S_{bg}(\alpha)$ around their median.

One observes in Fig. 9 that the CITS signature of the six matched circle pairs at $\alpha = 31.1$ is only slightly above this background in the worst case simulation. Since the measurements contain residual foregrounds not taken into account by our simulations, which further

Figure 9. The CITS correlation $S(\alpha)$ is calculated for 100 different 3-torus simulations with $L = 4.0$ using the beam profile and the detector noise of the $V$ band. The CMB maps are smoothed using the parameters $\theta = 0.4$ (panel a) and $\theta = 0.5$ (panel b) and downgraded to $N_{\text{side}} = 256$. The blue dotted curve shows the maximum of $S(\alpha)$ taken over all 100 simulations. The red full curve shows the corresponding minimum and represents thus the worst case occurring in the 100 simulations. The shaded band encompasses all values of $S_{bg}(\alpha)$ occurring in the 100 simulations, while the grey band contains 66 per cent of the $S_{bg}(\alpha)$ values around their median. This reveals the variation of $S(\alpha)$ with respect to the random initial conditions of the CMB simulations.

deteriorate the signal, it seems that even the detection of matched circle pairs around $\alpha = 30'$ cannot be assured. For larger ring radii $\alpha$, see the signature at $\alpha = 52.7$ in Fig. 9, the situation is far better, and such matched circle pairs should be detected.

6 CITS SIGNAL FOR THE W AND V BANDS USING MASKS

The noise is not the only problem for the CITS signature, since foreground sources dominate the CMB in some parts of the sky so that the CMB signal cannot be reliably reconstructed. The way out found in the literature consists of masking the problematic sky regions in the CMB map and replacing the temperature values by those of the ILC map. Here, we do not use the pixels which are too severely contaminated by foregrounds and compute the CITS correlation only with those pixels which are lying outside the KQ75 and KQ85 masks provided by the WMAP team (Bennett et al. 2012). Thereby arises the problem that the values of the CITS correlation cannot be compared for circles having the same radius $\alpha$, since the correlations are computed from a different number of pixels depending on the orientation of the circles with respect to the mask. In a given HEALPix resolution $N_{\text{side}}$, a circle of radius $\alpha$ has the ring index $n_{\text{ring}}$ in the RING scheme (Görski et al. 2005) of the HEALPix map, i.e. $n_{\text{ring}} = n_{\text{ring}}(\alpha)$. Define the number $n_{\text{eff}}$ as the number of pixels that are used for the computation of the CITS correlation, that is $n_{\text{eff}} \leq n_{\text{ring}}^{\text{max}} = 4 \min(n_{\text{ring}}, N_{\text{side}})$ for $n_{\text{ring}} \leq 2N_{\text{side}}$ with equality for the case that the mask does not affect any pixel on the ring. The correlation $S(\alpha)$ is then analysed on the two-dimensional grid $n_{\text{eff}}$ versus $n_{\text{ring}}$.

According to the results of the preceding sections, the foreground reduced V- and W-band maps (Bennett et al. 2012) of the final nine-year data are expanded in the resolution $N_{\text{side}} = 512$ with respect to $n_{\text{eff}}$ and then are smoothed according to equation (4). This yields the CMB maps which are analysed in the following subjected to the KQ75 or KQ85 9 yr mask. The analysis of Bielewicz & Banday (2011) refers to the seven-year WMAP data subjected to the KQ85 seven-year mask. They take only those circle pairs into account for which less than half the length of each circle is masked. Our analysis differentiates much finer the statistical significance of the masked parts by separating the correlations $S(\alpha)$ with respect to $n_{\text{eff}}$. Thus, only correlations based on a similar number of structures along a circle are compared because of the equal area pixelization.

We analyse the CMB maps with the resolution $N_{\text{side}} = 256$ for the smoothing parameters $\theta = 0.4$ and $0.5$ by computing the CITS correlation $S$ as a function of $n_{\text{ring}}$ and $n_{\text{eff}}$. We do not find a pronounced peak in the data which could be interpreted as a signal for a matched circle pair.

Although our tests with the topological simulations discussed in the previous sections suggest otherwise, we nevertheless searched in the lower resolution $N_{\text{side}} = 128$ for peaks. This differs from the search in the $N_{\text{side}} = 256$ maps by putting the average of four $N_{\text{side}} = 256$ pixels into one $N_{\text{side}} = 128$ pixel. By this additional averaging the detector noise is suppressed more than necessary according to our simulations. However, a possible residual foreground signal on small scales would also be smoothed out thereby reducing its contribution to the $m$-weighted circle signature defined in equation (1). Figs 10 and 11 present the results for the CITS search in the $N_{\text{side}} = 128$ maps. In Fig. 10, the value of the CITS correlation is encoded by brightness. As already discussed, the horizontal axis $n_{\text{ring}}$ corresponds to the radius $\alpha$ of the circle in the $N_{\text{side}} = 128$ resolution, while the vertical axis over $n_{\text{eff}}$ separates the CITS values with respect to the number of pixels on which its calculation is based.

Towards smaller values of $n_{\text{eff}}$, the CITS value and correspondingly the brightness increases, in general, because a lower number of pixels enhance the probability of a large correlation by chance. A pronounced peak occurs at $n_{\text{ring}} = 202$ corresponding to $\alpha = 73.7$ and $n_{\text{eff}} = 188$. Its position is marked by an arrow in Fig. 10. A further peak at the position $n_{\text{ring}} = 72$ corresponding to a smaller ring with $\alpha = 26.6$ and $n_{\text{eff}} = 256$ is also marked. Although CITS values belonging to different values of $n_{\text{eff}}$ cannot be strictly compared due to their different significance, we nevertheless combine two stripes with $n_{\text{eff}}$ in [175, 250] and $n_{\text{eff}}$ in [250, 500] by taking the maximum in the given $n_{\text{eff}}$ interval for a fixed value of $n_{\text{ring}}$. The results are plotted in Fig. 11 for both stripes for the V- and W-band maps subjected to the KQ75 and KQ85 masks. Panel (a) reveals the pronounced peak at $n_{\text{ring}} = 202$. The signal is visible in all four cases shown in the figure. A further peak in panel (a) at $n_{\text{ring}} = 90$ emerges only by using the KQ75 mask and is absent using the KQ85 mask. The decrease in the CITS correlation is thus caused by pixels close to the boundary of the KQ75 mask. This case demonstrates...
The circles-in-the-sky test

Figure 11. The CITS correlation $S(\alpha)$ shown in Fig. 10 is shown as a one-dimensional plot by taking the maximum of $S$ over the stripe $n_{\text{eff}} \in [175, 250]$ in panel (a) and over the stripe $n_{\text{eff}} \in [250, 500]$ in panel (b). The peak at $n_{\text{ring}} = 202$ visible in panel (a) is marked by the right arrow in Fig. 10. The left arrow corresponds to the peak at $n_{\text{ring}} = 72$ seen in panel (b).

that a few additional pixels can destroy a CITS signal. The peak at $n_{\text{ring}} = 72$ shown in panel (b) is more clearly seen in the $W$-band data but is independent of the mask.

It is instructive to discuss the position of the circle pair on the CMB map. The large circle pair with $n_{\text{ring}} = 202$ lies in the neighbourhood of the galactic plane as shown in Fig. 12(b). This is the reason why large parts of this circle pair are excluded by the mask. In addition, this location bears the risk that many pixels used in the computation of the CITS correlation contain significant amounts of foreground contributions. The situation is more favourable in the case of the smaller circle pair with $n_{\text{ring}} = 72$ shown in Fig. 12(a). This pair is far away from the galactic plane and most pixels are taken into account. At $n_{\text{ring}} = 72$, one has $n_{\text{eff}}^{\text{max}} = 288$ which is close to $n_{\text{eff}} = 256$ found for this circle pair. On the other hand, the simulations of the preceding sections demonstrate that a circle pair with such a small radius is at the detection threshold.

The CITS signatures in the resolution $N_{\text{side}} = 128$ at $n_{\text{ring}} = 72$ and 202 are probably generated by chance. This is suggested by a comparison with the results in the resolution $N_{\text{side}} = 256$ where these circle pairs reveal no unusual high correlation values. Furthermore, we add the V- and W-band maps after correcting for their different beam profiles. After smoothing the summation map with $\theta = 0.5$, it is downgraded to $N_{\text{side}} = 256$. The maximum of the correlation $S$ with $n_{\text{eff}} \geq 300$ is plotted in Fig. 13 as the full curve, where the KQ85 mask is used. The values of $n_{\text{ring}}$ for $N_{\text{side}} = 256$ are twice that of $N_{\text{side}} = 128$ for the same radii $\alpha$. So peaks around $n_{\text{ring}} = 144$ and 404 would be expected from the $N_{\text{side}} = 128$ results. Although a peak at $n_{\text{ring}} = 140$ appears, it has nothing to do with that in the $N_{\text{side}} = 128$ resolution, since its circle pair has a different orientation. Furthermore, this peak is absent if the KQ75 mask is used. Fig. 13 also shows as a dotted curve the CITS correlation for a torus model with $L = 4.0$ having circles at $\alpha = 31:1$ ($n_{\text{ring}} = 168$ for $N_{\text{side}} = 256$) and at $\alpha = 52:7$ ($n_{\text{ring}} = 279$ for $N_{\text{side}} = 256$). The large circles at $n_{\text{ring}} = 279$ are clearly revealed, while none of the six small circle pairs at $n_{\text{ring}} = 168$ leads to enhanced correlation values. The fact that the circle pairs at $\alpha = 31:1$ are not detected...
suggests that the peak at \( n_{\text{ring}} = 140 \) corresponding to \( \alpha = 25.8^\circ \) is produced by chance and possible contributions from foreground sources. Furthermore, this fact also shows that matched circle pairs should have radii larger than \( \alpha = 30^\circ \) in order to be detectable with WMAP data.

Although the CITS peaks of the two matched circle candidates cannot be confirmed in the \( N_{\text{side}} = 256 \) resolution, it is instructive to compare the \( N_{\text{side}} = 128 \) CITS signature with the 100 simulations that were used in Section 5, see also Fig. 9, to estimate the detection threshold in the case without mask. These 100 3-torus simulations take the beam profile and the detector noise of the \( V \) band into account, and in the following, only the smoothing \( \theta = 0.5^\circ \) is considered. The 100 CMB maps were downgraded to \( N_{\text{side}} = 128 \), and the background amplitude \( S_{bg} \), see equation (5), is computed for each of the 100 maps. The maximum taken from the 100 values of \( S_{bg} \) estimates the detection threshold in the sense that if a CITS signal higher than this threshold occurs, its probability would be lower than 1:100 in comparison with the simulations. In contrast to the detection threshold with mask, shown in Fig. 9, the maximum over the 100 \( S_{bg} \) curves is no longer a relatively smooth curve, but instead shows large fluctuations which are caused by the selective behaviour of the mask. Therefore, also the 5th and 10th highest values of the 100 \( S_{bg} \) values are computed leading to much smoother curves. The results are presented in Figs 14 and 15 for the KQ75 9 yr and KQ85 9 yr mask, respectively. One observes that both matched circle pair candidates, the one belonging to \( n_{\text{ring}} = 72 \) corresponding to \( \alpha = 26.6^\circ \) and the other one belonging to \( n_{\text{ring}} = 202 \) with \( \alpha = 73.7^\circ \), take on values larger than \( S_{bg} \) in any of the 100 simulations. Comparing these two peaks in the CITS correlation with the 5th or the 10th highest \( S_{bg} \) value reveals an even higher excess. Furthermore, the results do not seem to depend on the chosen mask, since the KQ85 mask as well as the more restrictive KQ75 mask leads to similar conclusions. Note that the 5th or the 10th highest \( S_{bg} \) value provides an upper envelope of the \( V \)- and \( W \)-band results with only a few exceptions. This demonstrates that the height of the two peaks is indeed unusual. However, since the peaks possess no correspondence in the higher resolved \( N_{\text{side}} = 256 \) CMB maps, they are probably not a genuine topological signature. As shown above, our simulations with the characteristics of the \( V \)- and \( W \)-band maps reveal a stronger topological signature in the \( N_{\text{side}} = 256 \) maps contrary to the behaviour of the two CITS candidates. A loophole in this conclusion might be that the \( V \)- and \( W \)-band maps could possess residual foregrounds on such small scales that their degrading contribution to the CITS signal is almost eliminated in the low-resolution \( N_{\text{side}} = 128 \) CMB maps but not in \( N_{\text{side}} = 256 \) CMB maps.

7 SUMMARY AND DISCUSSION

The CITS signature provides a test for a possible non-trivial topology, i.e. for a multiply connected space, of our Universe. The detection threshold of a matched circle pair depends on the radius \( \alpha \) of the circle. In order to determine the detection threshold, accurate

\end{figure}
CMB maps are simulated for the 3-torus topology, and their CITS correlations are computed for various circumstances.

The CITS correlation is introduced in equations (1) and (2) in Section 2. This topological detection measure is applied to a simulated 3-torus CMB map for a restricted search for back-to-back circle pairs. It turns out that for radii $\alpha \gtrsim 25^\circ$, the CITS signal is strong enough for a detection of matched circle pairs. Furthermore, it is found that the highest correlation values are not found on the matched circles, but rather for neighboring circles having slightly smaller radii. The smaller the radii of the matched circle pairs, the more pronounced is this effect.

The experiments provide CMB maps in which the resolution is determined by the size of the pixels. Section 3 investigates the question how an additional Gaussian smoothing of the CMB data can enhance the detection probability for a matched circle pair. The amplitude of the CITS signal is compared with the detection threshold for several CMB simulations with different HEALPix resolutions $N_{\text{side}}$ and different Gaussian smoothing parameters $\theta$, see equation (3). This analysis leads to the conclusion that for $N_{\text{side}} = 256$, a smoothing parameter of $\theta = 0.4$ is preferable if the pixels contain the clean CMB signal. But for $N_{\text{side}} = 512$, one should prefer a smaller smoothing parameter $\theta$ in order to detect also matched circle pairs with smaller radii. Experimentally, such clean sky maps are not available because of detector noise and residual foregrounds.

Before these problems are addressed, we turn in Section 4 to the question how sharp the peaks are which belong to genuine matched circle pairs. This determines the resolution of the search grid $N_{\text{grid}}$ whose coordinates are used as possible circle centres for which the CITS correlation is computed. It is demonstrated that for a smoothing of $\theta = 0.4$, several matched circle pairs get missed at $N_{\text{grid}} = 128$ while using $N_{\text{side}} = 512$ for the CMB map. Moreover, one can find matched circle pairs at $N_{\text{grid}} = 128$, one cannot exclude matched circle pairs if no circle pairs are found at this search grid resolution.

In Sections 2–4 only general properties are studied without reference to a specific experiment. In Section 5, however, CMB maps for the 3-torus topology are generated which take the noise properties of the V- and W-band channels of the WMAP satellite into account. The CITS correlation for a CMB map having the quality corresponding to the WMAP 9 yr observations is computed in the $N_{\text{side}} = 512$ resolution. It turns out that the CITS signal of the matched circle pairs is either absent or very faint which demonstrates that the noise is too severe in order to search directly in the original V- and W-band maps for a topological signature. This result is further substantiated by smoothing the $N_{\text{side}} = 512$ map using the parameters $\theta = 0.4$ and 0.5. These additionally smoothed $N_{\text{side}} = 512$ maps reveal the CITS peaks at the positions of the matched circle pairs. Such a smoothing is necessary for a sufficient suppression of noise. Since the above conclusions are based on a single CMB simulation, a set of 100 CMB maps is generated for the 3-torus topology with side length $L = 4$. Their 100 CITS correlations reveal the variability with respect to the Gaussian random initial conditions which determine how the eigenmodes are weighted. As shown in Fig. 9, the variability of the height of the CITS peaks at circle radii around $\alpha \approx 30^\circ$ is so important that some matched circle pairs are at detection limit. Around $\alpha \approx 50^\circ$ the variability is of the same order, but the detection probability is not affected due to the more pronounced peaks.

The results of Sections 2–5 are obtained from simulations for only two different side lengths $L$ of the 3-torus topology. Although the magnitude of the CITS correlation does not directly depend on the side length $L$, the detection probability depends on it through the simple fact that smaller topological sizes lead to more matched circle pairs which in turn enhances the discovery probability. The dependence on the cosmological parameters is also modest because of the small range of variability available for them due to the current accurate measurements. Furthermore, the results apply only to back-to-back searches since the general search leads to a much higher background level because of the vast increase in possible combinations of circle pairs.

Section 6 addresses as a further complication the residual foregrounds which can be so severe that it is advisable to mask the unsafe regions. As a consequence, the CITS correlation can only be computed from the unmasked fraction of the circle leading to a statistical significance depending on the number $n_{\text{pix}}$ of pixels used for the computation of the CITS correlation. The search for a CITS signature in the foreground reduced V- and W-band maps with $N_{\text{side}} = 256$ and $\theta = 0.4$ or 0.5 subjected to the KQ75 or KQ85 mask yields a negative result. Although the results obtained from our simulation would not advise to use the $N_{\text{side}} = 128$ resolution in a CITS search, we nevertheless carry out the $N_{\text{side}} = 128$ search and find some interesting peaks. A peak emerges from the background at the large circle radius $\alpha = 73.7$ as seen in Figs 10, 11(a), 14(a) and 15(a). The corresponding circle pair lies, however, as seen in Fig. 12(b), very close to the galactic plane. Since one expects the largest residual foregrounds close to the galactic plane, the suspicion arises that the signal might be spuriously generated by residual foregrounds. However, if one accepts such an argument, the reverse argument that these very residual foregrounds can also destroy a true CITS signal has to be accepted in the same way. Furthermore, since so many pixels are masked in this circle pair, the high CITS correlation could also be produced by chance. But the simulations presented in Figs 14(a) and 15(a) demonstrate that the amplitude of the peak is indeed unusual. A second interesting peak in the CITS correlation belongs to a circle radius $\alpha = 26.6$, which is also probably generated by chance as our simulations show. On the other hand, this circle pair is far from the galactic plane, and a few pixels are masked and the residual foregrounds are less important. As demonstrated in Section 6, the six circle pairs at $\alpha = 31.1$ in the $L = 4.0$ torus topology are not detected by using the quality of the WMAP data, which shows that matched circle pairs have to be larger than at least $\alpha = 30^\circ$ in order to be detectable. We are thus eagerly awaiting new more accurate data in order to see whether the CITS peaks will withstand or prove to be a spurious result. Even if these CITS signatures will not endure, a multiply connected space can possess circle pairs that are not back to back and these are not considered in this paper. Examples for topologies with such generic matched circle pairs are provided by the half-turn space $E_2$ (Aurich & Lustig 2011) and by spherical double-action manifolds (Aurich & Lustig 2012a,b). These spaces would require an extended search for generic matched circle pairs.
