THE EFFECT OF THERMAL MODIFICATION ON THE DEVELOPMENT OF CARBON MATERIAL MICROPOROUS STRUCTURE

B.K. O斯塔ficWuk, I.M. Budzulyak, N.Ya. Ivanichok, B.I. RachiY, R.P. Lisovsky

Abstract: A research is done to characterize the microporous structure of outgoing and thermally modified (673 K, 180 min) plant-extracted carbon material. The porous system characteristics are worked out by different methods on low temperature (77K) N$_2$ adsorption-desorption based isotherm. It is stated that thermal modification contributes to the enlargement of specific surface (from 361 m$^2$/g to 673 m$^2$/g), an increase in total pore volume (from 0,166 cm$^3$/g to 0,477 cm$^3$/g) and an increase in micropore volume (from 0,127 cm$^3$/g to 0,173 cm$^3$/g). Most effectively thermal modification is apt to form nanopores with diameters of 0,75; 1,25 and 4 nm.

Keywords: porous carbon material, thermal modification, low temperature porometry, structural and adsorptive characteristics.

1. INTRODUCTION

Porous carbon material (PCM) possesses unique physical and mechanical properties and is widely used – from nanoelectronics and supercapacitors to composite material [26, 5]. Providing carbon material with necessary electrical and physical properties, apart from those which are defining for the material-based electrochemical capacitors, is carried out both in the course of its obtaining and by way of chemical and thermal treatment of carbonized material [4]. Traditional raw materials for the production of quality PCM is hardwood, fruit seeds, coconut peel, coal, and resins with high-content coal and natural micro- and mesoporosity [10].

From the point of view of its practical use the conspicuous characteristics PCM are internal pore volume, the specific surface and volume of micropores. The simplest and most reliable method of measuring these characteristics is gas sorption. Gas sorption measurement is easy to install and use.

The goal of figuring out the specifics of application of N$_2$ adsorption-desorption to characteristics of PCM porous structure is to assess the impact of its thermal characteristic versions to the carbon material, obtained from apricot pits; and to analyze applicability of different methods of calculation for the characteristics of carbon material porous structure.

2. EXPERIMENT AND DISCUSSION

The object of research is the process of forming carbon material porous structure in the course of its obtaining and further thermal modification. The subject of research is the PCM, obtained by
hydrothermal carbonization of apricot pits-extracted material under the pressure of water vapour (12-15)-10^5 Pa. The temperature range of carbonization activation totalled 873-1273 K. Thermal activation is carried out 3 h at temperature 673 ± 3 K that leads to obtaining the samples, the symbols being listed in Tab. 1.

| Temperature carbonating activation, K | Samples after carbonation activation | Samples after thermal activation at 673 K |
|--------------------------------------|--------------------------------------|----------------------------------------|
| 873                                  | CA - 1                               | CTA - 1                                |
| 973                                  | CA - 2                               | CTA - 2                                |
| 1073                                 | CA - 3                               | CTA - 3                                |
| 1173                                 | CA - 4                               | CTA - 4                                |
| 1273                                 | CA - 5                               | CTA - 5                                |

Tab. 1. Marking of PCM samples

A microscopic research is done by means of the e- microscope Zeiss Supra 40 VP (Carl Zeiss Group Germany) with a field cathode (Field Emission), e-microscope GEMINI and a fully oil-free vacuum system with the mode of operation on low vacuum (VP).

Determination of PCM structural and adsorptive characteristic is carried out by means of Nisorption at temperature T = 77 K on the automatic sorptometer Quantachrome Autosorb (Nova 2200 e). The samples have been degased at 453 K during 20 hours.

The following methods are employed to calculate the parameters of CA and CTA porous structure: 1) proposed by Brunauer, Emmett, Teller [3] BET method in boxes, with a limited range of relative pressure \( P/P_0 = 0.05-0.035 \); 2) the method of Langmuir (method L) [13], which is based on the assumption that the adsorbent saturation limit corresponds to the formation of a monolayer of nitrogen, and 3) the method of BJH, proposed by Barret, Joyner and Halenda [1], and 4) the method of DH, the proposed Dollimore and Heal [7]; 5) t-method [6] and its modification MR method [21] to determine the micropore size distribution; 6) \( \alpha_s \)-method [11]; 7) the method of DR- method [8]; 8) HK-method proposed by Horvath and Kawazoe, which calculates the size of the region of small micropores relative pressure adsorption isotherm and is designed for materials, which is dominated by slit-like pores [12]; 9) method SF, developed by Saito and Foley for cylindrical micropores [27]; 10) method DFT (Density functional Theory), which is based on density functional theory [9].

Here are the parameters that characterize carbon material porous structure: \( S \) (m\(^2\)/g) – specific surface volume; \( V_c \) (cm\(^3\)/g) – the total volume calculated by the volume of adsorbed nitrogen at \( P/P_0 > 0.995 \); the volume of micropores \( V_m \) (cm\(^3\)/g) is calculated by a t-method, external surface area \( S_{ext} \) (m\(^2\)/g) and micropore surface \( S_m \) (m\(^2\)/g) by the formula \( S_m = S_{BET} - S_{ext} \); \( d \) (nm) – an average diameter or width of the pores.

In the study of PCM structural properties important is the shape and size of micro- and nanopores formed in the material as a result of technological operations in the course of their obtaining and further treatment. In Fig. 1 is a SEM-image of BK-3 carbon material surface at different scales. When considering the PCM surface (Fig. 1) one can see surface microgaps, round and oval transport pores, which in most cases are filled with fragments of coal fractures. The entire surface observes white inclusions which are the main source of metal, oxygen , and the remnants of burnt cinder [24].
The effect of thermal modification of carbonized carbon material is done at temperature (673 K, 180 min), followed by the opening of porous structure (Fig. 2) which has been invisible before treatment in contrast to the outgoing material surface with separate outputs of pores. The reason for this structure is that organic substance of the material surface is burned in the course of obtaining carbon from a plant-extracted material, but the remnants rise along the channels (pores) from grains onto the surface under vapour pressure. Thus, thermal activation makes it possible to cleanse coal surface from organic and adsorbed remnants that result in new pores and an increase of porosity.

Fig. 1. The microstructure of the surface of carbonated PCM
Fig. 2. SEM-surface image of CTA-3 samples

Fig. 3 shows typical isotherms of N$_2$ adsorption for CA-3 and CTA-3 samples which belong to the isotherms of type II and can be observed in polmolecular adsorption [20]. It is hysteresis that is observed in CTA-3 samples (type H4 by IUPAC classification [11]) which is usually associated with capillary condensation in mesopores. The point of branching adsorption and desorption curve is observed at p/p$_0$ $\approx$ 0.42, where p and p$_0$ – vapour pressure of N$_2$ adsorbate and pressure of its saturated pore at 77 K, respectively. Hysteresis as well as another phenomenon can be observed in CA-3 samples which is manifested as the discrepancy between the branches of adsorption and desorption in a relatively low pressure and is called the hysteresis of low pressure. There are several possible reasons.
for its manifestation: swelling of spatial highly molecular frame of adsorbent, permanent retention of adsorbent molecules in pores, the size of which is close to adsorbate molecules; permanent chemical interaction of adsorbate and adsorbent [11].

![Graph](image)

**Fig. 3. Isotherms of N₂ sorption (77 K) for CA-3 (–□–) and CTA-3 (–●–)**

As the isotherms of carbonized PCM adsorption -desorption samples (samples CA) are similar, they are not shown in this work.

Fig. 4 shows the isotherms of carbon material N₂ adsorption after its thermal activation (samples CTA). For all the samples the isotherms belong to those that are characterized by the presence of hysteresis loops. The analysis of the isotherms makes it possible to trace the impact of thermal activation on the development of activated carbon porous structure.

![Graph](image)

**Fig. 4. A N₂ sorption isotherm (77 K) for thermally modified PCM: –□– CTA-1; –●– CTA-2; –Δ– CTA-3; –▽– CTA-4; –0– CTA-5**

As a quantitative measure of hysteresis ($\Delta V_H$) the difference of N₂ adsorbed volume is taken from isotherms of desorption ($V_{de}$) and adsorption ($V_{ad}$) at $p/p_0 = 0.7$: $\Delta V_H = V_{de} - V_{ad}$. Estimates of low pressure hysteresis ($\Delta V_{LPH}$) held at $p/p_0 = 0.2$: $\Delta V_{LPH} = V_{de} - V_{ad}$.

In Fig. 5 is the dependence of hysteresis temperature on PCM temperature obtained. It can be seen in the Figure that carbonized coal material structural properties responsible for hysteresis phenomenon all over the range of temperatures, and in the interval 973-1073 K do not substantially change ($\Delta V_{LPH} = 6 \text{ cm}^3/\text{g}$, $\Delta V_H = 3 \text{ cm}^3/\text{g}$). Hysteresis in low pressure for CTA samples is actually not manifested, and values of $\Delta V_{LPH}$ are to close to nil. Hysteresis in high relative pressure ($p/p_0 = 0.42-1.0$) is manifested for all the samples, but value $\Delta V_H$ for CTA samples is lower than for CA samples.
Besides, the $\Delta V_H$ parameter for CTA samples rapidly changes with a temperature rise maximum at ~973 K that testifies to the maximum development of mesopores at this temperature (Tab. 2).

As is seen in Tab. 2, with temperature rise up to 1073 K the specific surface of $S_{\text{BET}}$ increases both for CA samples and CTA ones and reaches 673 m$^2$/g (CTA-3). At this value of specific surface of micropores $S_{\text{micro}}$ equals 406 m$^2$/g and their relative $V_{\text{micro}}/V_{\Sigma}$ content makes up 36% of the total volume of pores. For thermally activated material obtained at temperatures 1173-1273 K, the specific surface of $S_{\text{BET}}$ decreases to 626 m$^2$/g.

| Parameters       | Sample | Temperature, K |
|------------------|--------|----------------|
|                  |        | 873 (1) | 973 (2) | 1073 (3) | 1173 (4) | 1273 (5) |
| $S_{\text{BET}}$, m$^2$/g | CA     | 337     | 342     | 361     | 206     | 46      |

|                  | CTA    | 44      | 30      | 36      | 50      | 71      |

Tab. 2. Parameters of carbon material porous structure

In Fig. 6 is the distribution of pores by the size for CTA samples calculated in the terms of desorption with the BJH method. The distribution curves show that for all the thermo modified samples the major share in the total volume of pores is made up of pores with the radius 1.8-2.0 nm.
For these studies, to compare the parameters of porous structure and their influence on the specific characteristics of PCM have been selected samples of CA-3 and CTA-3.

The outgoing experimental basis for all theoretical calculations and interpretation is a sorption isotherm (Fig. 3) of samples of a given mass, i.e. the dependence of the number of evenly sorbed by the sample \( \text{N}_2 \) (under normal conditions) on the relative pressure of gaseous \( \text{N}_2 p/p_0 \). The characteristics of carbon material porous structure are defined by these isotherms, the values of which are calculated through different methods (Tab. 3).

| \( V_{s}, \text{ cm}^3/\text{g} \) | CA-3  | 0.166 | 0.005 | 0.005 | — | — | — | — | — | — | — |
|          | CTA-3 | 0.477 | 0.286 | 0.279 | — | — | — | — | — | — | — |
| \( V_{\text{micro}}, \text{ cm}^3/\text{g} \) | CA-3  | — | — | — | 0.127 | 0.130 | 0.161 | 0.162 | 0.148 | 0.148 |
|          | CTA-3 | — | — | — | 0.173 | 0.188 | 0.297 | 0.322 | 0.284 | 0.285 |
| \( V_{\text{micro}}/V_s \), % | CA-3  | — | — | — | 77 | 78 | 97 | 98 | 89 | 89 |
|          | CTA-3 | — | — | — | 36 | 39 | 62 | 68 | 60 | 60 |
| \( d, \text{ nm} \) | CA-3  | 1.84 | 3.22 | 3.22 | — | — | 2.55 | 1.74 | 0.37 | 0.45 |
|          | CTA-3 | 2.84 | 3.89 | 3.89 | — | — | 1.86 | 1.22 | 0.37 | 0.45 |

The specific surface area of \( S \) calculated by means of multipoint BET in the linear schedule of dependence \( 1/[W(p/p)-1] \) on \( p/p_0 \) in the range of an adsorption isotherm for the relationship \( p/p_0 \) within 0.05-0.35 equals 361 \( \text{m}^2/\text{g} \) and 673 \( \text{m}^2/\text{g} \) for CA-3 and CTA-3 samples, respectively. In CTA-3 sample the magnitude of the surface area and the total volume of pores is about 3 times greater than the corresponding values CTA-3 (0.477 \( \text{cm}^3/\text{g} \) and 0.166 \( \text{cm}^3/\text{g} \) calculated under \( p/p_0 = 0.99 \) in assumption...
that all the pores have been filled with liquid adsorbate). From the data obtained one can conclude that
the porous structure of CTA-3 is developed better than that of CA-3.

The researches [14, 19, 22, 23] read that it is incorrect to apply the BET method for the study of
microporous samples as its use is limited while defining the specific surface of pores of the sample
under study, micropores are taken out of account. This is why in commercial devices (Autosorb-type
and other analogues) L- DR-, t-, and αs-methods are widely used in the investigation of micropore-
content objects, in particular, in defining the surface area of microporous material the L-method is
applied which in contrast to the BET method gives for CA-3 and CTA-3 samples higher values of the
specific area of surface (~440 m²/g and 820 m²/g, respectively).

To assess the volume of micropores in the presence of meso-, and macropores the t-method is
often applied, in which the outgoing sorption isotherm is rebuilt as the function of a new variable t.
The latter value is called the statistical thickness of the adsorption film and is determined by the
following expression: \( t = \left( \frac{W}{W_{\text{mono}}} \right) \sigma \) where \( W \) – amount of adsorbed vapor, depending on the relative
pressure \( p/p_0 \); \( W_{\text{mono}} \) – the capacity of a monolayer on the surface of the sample; \( \sigma \) – monomolecular
thickness adsorption film (for nitrogen at \( T = 77 \) K is assumed to be 0.354 nm [11]). Calculated like this
values for \( t \). are a good match even to the samples different by the chemical nature of the surface
[17, 18]. For carbon adsorbents, first of all, soot, the authors [18] recommend to make use of an equation
for the statistical thickness of adsorbed film proposed in ASTM D-6565-01 [28] standards.

For microporous samples a dependence plot of the volume of gas absorbed in normal conditions on
\( t \) is a straight line which cuts off the segment of the vertical axis for calculation of micropore volume
\( V_{\text{micro}} \). According to the slope of the line calculated value of the external specific surface area of the
sample \( S_{\text{ext}} \) (Fig. 7).

![Fig. 7. t-method for N₂ adsorption in CTA-3 sample](image)

The volume filling of micropores is completely neglected in the theory of t-method, as it is assumed
that it happens at considerably smaller relative pressures of gaseous N₂ on condition the statistical
thickness of adsorptive layer remains small. To check the correctness of applying the t-method, the data
obtained are compared with the results received from \( \alpha \)-method, and the DR-method which is based
on the theory of volume filling of micropores [8].

The comparison of different methods for porous structure parameters is carried out for thermally
activated carbon CTA-3 sample. Defined by BET-, DR-, DFT- and t-methods the specific surface values
are pretty close and are in the interval \( S = 609-674 \) m²/g, which means these methods can be applied for
defining the surface area of plant-extracted activated carbon.

There is a good for microporous materials co-ordination of the parameters of standard t-method
with BET-method that has also been observed for CTA-3 sample under study, for one of the known
ways to define external surfaces in microporous samples lies in the initial filling of some substance with
the following definition of the sample specific surface by BET-method [11]. Quite different are the
results obtained after correction of sorption isotherms on the volume of micropores calculated
according to DR-method. These isotherms by the shape markedly deviate from classical, and BET is not
The effect of thermal modification of microporous materials was studied. The values of specific surface differ considerably (Tab. 3) from the values of external specific surface defined by the t-method or BET-method.

A similar pattern is observed when determining the total volume of pores and the volume of micropores. BJH- and DH methods give a lower value $V_\Sigma = (0.286-0.279 \text{ cm}^3/\text{g})$, than the value of the total pore volume calculated at $p/p_0 = 0.99$ (Tab. 3). Methods HK and SF give a dose value $V_{\text{micro}} = 0.28 \text{ cm}^3/\text{g}$ though the former provides the presence in the material of Z-shaped pores, and the SF-method cylindrical. This value is close to the volume of micropores defined by DR- and DA-methods (Tab. 3). The proportion of micropores defined by DR-, DA-, HK- and SF-methods is 60-68% of the total volume of pores $V_\Sigma$. The ratio $V_{\text{micro}}/V_\Sigma$ for the value $V_{\text{micro}}$ obtained by t- and $\alpha_s$-method give lower results. It should be noted that the listed methods are often applied for defining the parameters of activated carbon materials porous system and carbon nanotubes [15, 16].

The obtained difference in micropore volumes for one and the same sample by t-method ($\alpha_s$-method) and DR (DA)-method is probably that in addition to micropores, mesopores also contribute to the defined volume by DR-method increasing the obtained value $V_{\text{micro}}$. A similar pattern is described in the works by the authors [2, 15, 25] who conduct a comparison of micropore volumes obtained by different methods for several samples of activated coal. For most coal volume value of micropores defined by t- and $\alpha_s$-method exceeds the corresponding magnitudes calculated by the DR-method. These samples contain micropores but do not have mesopores. At the same time there is a reverse ratio for PCM with both micropores and mesopores: the volume of micropores, defined by the DR-method, is larger than the values calculated by t- and $\alpha_s$-method and are observed for our PCM samples. This can be explained by the fact that the DR-method takes into account both micropores and mesopores.

The average diameter of pores for CTA-samples defined by BJH and DH methods is the same and equal to 3.89 nm, though the diameter obtained by the DR-method has substantially less value (1.86 nm). The HK method leads to low values ($d = 0.3$ nm) which by metric order approach to the defects of three-dimensional structure of solids, vacancies, in particular. The SF method gives average values of the diameter which are smaller than those for ultra micropores ($d \leq 1.4$ nm). However, it is unlikely that the porous system of our samples has only represented those pores.

Thermal activation significantly changes the dependence character of the total volume of pores on the diameter of pores (Fig. 8) calculated by the isotherms of desorption through the BJH method which is usually used for estimation of pore distribution by the size [16]. Thermal activation of the original raw material contributes to the increase in the volume of pores of all sizes and develops the pore diameter in the vicinity of 4 nm.

![Fig. 8. Dependence of pore volume on their diameter (BJH method) for samples: 1 - outgoing (CA-3); 2 - thermally activated (CTA-3)](image_url)
The investigation of micropore distribution by the size was carried according to MP- and DFT methods. One can conclude from the MP method of distribution that thermal modification initiates formation of diameter pores < 2 nm with maximum in the vicinity of 0.75 nm (Fig. 9).

![Fig. 9. Distribution of micropores by the size (MP method)](image)

Classical theories such as DR and DA and half empirical approaches, HK and SF in particular, do not fully describe the filling of micropores and narrow mesopores. This leads to an understatement of the true size and error in calculation. A modern approach to the description of adsorption isotherms and pore distribution by the size for microporous materials is based on quantum-mechanical calculation. The essence of the approach is to construct theoretical isotherms for different pores of microporous adsorbent-adsorbate. Calculation is carried out according to the Density Functional Theory (DFT). The DFT method was used to get the distribution of PCM micro- and mesopores. The method takes into account the fundamental molecular parameters that characterize the interaction of gas-gas and gas-solid in the adsorptive system. The results obtained are presented as a set of bar charts in Fig. 10.

The DFT method makes it possible to determine the specific surface, the total pore volume, and their distribution both by the size and by the volume (Tab. 4). The obtained data (Fig. 10, Tab. 4) show that for CA-3 sample the contribution to the specific surface area and total pore volume is made only by micropores. Thermal activation of the CA-3 sample contributes to the development of micropore diameter ~ 1.25 nm and pore diameter ~ 4 nm.

![Fig. 10. Distribution of pores by the size (DFT method)](image)
The effect of thermal modification ...

| Parameter                        | CA-3 | CTA-3 |
|----------------------------------|------|-------|
| Specific surface area, m²/g      | 295  | 609   |
| Total pore volume, cm³/g         | 0.146| 0.426 |
| Micropore volume (d < 2 nm), cm³/g | 0.146| 0.221 |
| Surface area of micropores (d < 2 nm), m²/g | 295  | 522   |
| Average pore diameter, nm        | 1.29 | 3.97  |

Tab. 4. Structural and adsorptive characteristics of carbon material (DFT method)

Obtained by the methods MP (Fig. 9) and DFT (Fig. 10) dependencies for CA-3 and CTA-3 samples are quantitatively different due to differences in the physical models assigned at the core of these methods. But qualitatively both methods confirm that thermal activation contributes to the development of pores of a certain size.

3. CONCLUSIONS

Thus the temperature of synthesis is an important control of porosity that allows you to receive PCM with adjustable porous structure. Hydrothermal carbonization of apricot pits and further thermal activation of origin raw material forms a high specific surface and porous structure of carbon material. The optimal temperature synthesis of PCM from the enlarged area of micro- and mesopores is 1073 K. Under the conditions of thermal versions of origin raw material enlarges the specific surface area and porous structure of activated carbon, so do the diameter pores up to 5 nm. The most noticeable effect is observed for pores with diameters of 0.75, 1.25 and 4 nm.

To determine the specific surface of plant-extracted porous carbon material the BET-, t- and αs-methods are most correct. The DR method gives inflated values of the specific surface of micropores as compared to the t- and αs-methods. A possible reason for it that the DR method takes into account both micropores and mesopores.

Остафійчук Б.К., Будзуляк І.М., Іванічок Н.Я., Лісовський Р.П., Рачій Б.І. Вплив термічної модифікації на розвиток мікропористої структури вуглецевого матеріалу. Журнал Прикарпатського університету імені Василя Стефаника, 1 (1) (2014), 41–53.
Проведено порівняння характеристик мікропористої структури вихідного та термічно модифікованого (673 К, 180 хв) вуглецевого матеріалу із сировини рослинного походження. Дані характеристики пористої системи розраховані різними методами на підставі ізотерм низькотемпературної (77 К) адсорбції-десорбції азоту. Встановлено, що термічна модифікація сприяє розвитку питомої поверхні (з 361 м²/г до 673 м²/г), збільшенню загального об’єму пор (з 0,166 см³/г до 0,477 см³/г) і об’єму мікропор (з 0,127 см³/г до 0,173 см³/г). Найбільш ефективно термічна модифікація сприяє утворенню нанопор діаметром 0,75; 1,25 і 4 нм.

Ключові слова: пористий вуглецевий матеріал, термічна модифікація, низькотемпературна порометрія, структурно-адсорбційні характеристики.
