Abstract

In this work, we introduce the novel problem of identifying dense canonical 3D coordinate frames from a single RGB image. We observe that each pixel in an image corresponds to a surface in the underlying 3D geometry, where a canonical frame can be identified as represented by three orthogonal axes, one along its normal direction and two in its tangent plane. We propose an algorithm to predict these axes from RGB. Our first insight is that canonical frames computed automatically with recently introduced direction field synthesis methods can provide training data for the task. Our second insight is that networks designed for surface normal prediction provide better results when trained jointly to predict canonical frames, and even better when trained to also predict 2D projections of canonical frames. We conjecture this is because projections of canonical tangent directions often align with local gradients in images, and because those directions are tightly linked to 3D canonical frames through projective geometry and orthogonality constraints. In our experiments, we find that our method predicts 3D canonical frames that can be used in applications ranging from surface normal estimation, feature matching, and augmented reality.

1. Introduction

In recent years, learning to predict 3D properties from a single RGB image has made great progress. For example, monocular depth estimation \([34, 25, 47, 44, 12]\) and surface normal prediction \([10, 45, 3, 28]\) have improved dramatically. There are many applications of them in scene understanding and robot interaction.

The main challenge in this domain is choosing an appropriate representation of 3D geometry to predict. Zhang et al. \([52]\) predicts dense surface normals and then uses geometric constraints to solve for depths from them with a global optimization. GeoNet \([28]\) predicts both surface normals and depths and then passes them to a refinement network for further optimization. These methods are clever in their use of geometric constraints to regularize dense predictions. However, still they infer only 2 of the 3 degrees of freedom in a 3D coordinate frame – the rotation in the tangent plane around the surface normal is left unknown. As such, they are missing 3D information critical to many applications. For example, they cannot assist an AR system in placing a picture frame on a wall or a laptop on a table because they don’t know the full 3D coordinate frame (including tangent directions) of the wall and table surfaces.

In this work, we propose a novel image-to-3D task: pixel-wise local canonical frames estimation from a single image (figure 1). The orthogonal bases of the canonical frames include the surface normal plus two tangent principal directions generally following the principal curvatures of the surface. With an understanding of the local canonical frames, our task not only offers better surface normal estimation but also enables perspective-invariant feature descriptors and new applications in augmented reality. We propose to jointly estimate the projected tangent directions and canonical frames, and find that the joint estimation can...
improve the estimation of tangent principal directions and surface normals. We believe the reason is that tangent principal directions can be directly inferred from low-level features such as image gradients, since their projections are often aligned with the texture directions or object boundaries, as shown in figure 2(b).

In addition to surface normal estimation, the tangent principal directions are also important 3D properties, as they imply the canonical transformation that maps the 3D surface to the image plane. Thus, an inverse transform of the image patch could alleviate the perspective distortions. We show that this can improve local patch descriptors like SIFT [26] which is rotational and scale invariant but influenced by perspective. Further, understanding the perspective enables new applications in augmented reality, including inserting new elements on top of either flat or curved surfaces in the scene with the correct perspective distortion.

To make the learning practical, we need the ground truth local canonical frames labeling for RGB frames. We propose to use existing 3D reconstruction datasets like ScanNet [9] which offers alignment between images and 3D meshes. We can compute the canonical frames on the meshes and render them to the aligned RGB frames. We follow TextureNet [20] that computes tangent principal directions as the extrinsic four-way rotationally symmetric (4-RoSy) orientation field using QuadriFlow [21]. We find that the surface tangent directions computed this way are consistent enough to be learned by a network.

Overall, the core contributions of the paper are:

- Identifying an important new 3D vision problem: local canonical frames estimation from RGB images.
- Using projected tangent principal directions to improve canonical frames estimation, outperforming existing works on surface normal estimation.
- Exploiting tangent projected principal directions to compute perspective invariant feature descriptors.
- Inserting new elements in the scene in a manner aware of perspective distortions, for augmented reality.

2. Related Work

3D from Single Image. Estimating 2.5D geometry properties from a single image has become popular in recent years. Traditional methods aim at understanding low-level image information and geometry constraints. For example, Torralba et al. [41] exploits the scene structure to estimate the absolute depth values. Saxena et al. [33] uses handcrafted features to predict the depth based on Markov random fields. Hoiem et al. [18] recovers scene layout guided by the vanishing points and lines. Shi et al. [35] estimates the defocus blur and uses it to assist depth estimation.

With the availability of large-scale dataset and the success of deep learning, many methods have been proposed for depth or/and surface normal estimation. For depth estimation, Eigen et al. [11] uses CNN to predict indoor depth maps on the NYUv2 dataset. With the powerful backbone network architecture like VGG [37] or ResNet [16], depth estimation can be further improved [13, 46]. DORN [12] proposes a novel ordinary loss and achieves the state-of-the-art in KITTI [14]. For surface normal estimation, Wang et al. [45] incorporate vanishing point and layout information in the network architecture. Eigen and Fergus [10] trained a coarse-to-fine CNN to refine the details of the normals. The skip-connected architecture [3] is proposed to fuse hidden layers for surface normal estimation.

Since surface normal and depth are related to each other, another set of methods aimed at jointly predicting both to improve the performance. Wang et al. [43] exploits the consistency between normal and depth in planar regions. GeoNet [28] proposes a refinement network to enhance the depth and normal estimation from each other. Zhang et al. [52] predict the normal and solve a global optimization problem to complete the depth. We take a further step by jointly estimating all axes of a 3D canonical frame at each pixel, which helps both regularize the prediction through constraints and is useful in applications (see Sec. 5).

Local Canonical Frames Computing local canonical frames on surfaces is a fundamental step for many problems. 3DLite [19] builds canonical frames in fitted 3D planes for color optimizations. GCNN [27] defines local frames with spherical coordinates and applies discrete patch operators on tangent planes. ACNN [6] introduces the anisotropic heat kernels derived from principal curvatures so that it can apply convolutions in local canonical frames defined by principal axes. Such canonical frame is also used in Xu et al. [48] for nonrigid segmentation, by Tatarchenko et al. [39, 20] for semantic segmentation of the 3D scenes. We aim at recognizing such canonical frames from 2D images, and we compute them from 3D surfaces to supervise the learning.

TextureNet [20] highlights the challenges of comput-
ing robust local canonical frames at planar surface regions, where the principal curvatures are undetermined or highly influenced by noise or uneven sampling. Therefore, it proposes to compute a 4-RoSy orientation field to represent the principal directions. The 4-RoSy orientation field is an important concept in geometry processing community [30, 23]. The target directions are aligned with the principal curvatures [8, 7], but regularized by additional energy to vary smoothly. This can be achieved by optimizing a nonlinear energy by periodic functions [17, 29] or a mixed-integer representation [30, 5]. In our work, we use QuadriFlow [21] to optimize the 4-RoSy field so that it aligns with the principal curvatures at the curved surface and ensures smoothness in flat regions (where principal directions are ill-defined) as well as robustness to noise.

3. Approach

In this section, we develop our approach for learning local canonical frames from RGB images. First, we discuss the ground truth labeling of canonical frames from 2D images in section 3.1. Then, we discuss the concept of projected tangent principal directions in section 3.2. Finally in section 3.3, we propose several energy terms that enforce the neural network to predict consistent local canonical frames assisted by the projected tangent principal directions. Since we focus on the behavior of the local canonical frames rather than the neural network architecture, we can adopt any neural network that predicts per-pixel features (see experiments in Sec. 4 and 5).

3.1. Local Canonical Frames Generation

To label the canonical frames, we need a dataset with 3D meshes aligned with RGB images so that we can compute frames from geometry and render them to images to produce ground truth. We choose ScanNet [9] for our experiments.

We compute canonical frames as surface normals and tangent principal directions with the scene geometry. It is straightforward to compute surface normals, but tangent principal directions at flat regions are hard to compute especially in the presence of noise. As visualized in figure 3(a,c), the tangent principal directions can be pretty noisy. To solve this problem, we adopt the 4-RoSy field using QuadriFlow [21] as proposed by TextureNet [20], as shown in figure 3(b,d): This field generates consistent directions which vary smoothly at flatter regions and are aligned with the principal curvatures at curved surfaces. The cross-field is 4-RoSy since there are four valid choices for the tangent principal directions at each vertex. Considering this, we pick any pair of orthogonal tangent vectors in the cross field to represent the principal directions, but we also view the other three alternatives as valid ground truth.

Figure 3. (a) computes the direction field from estimated principal curvatures. Noises exist in both the geometry and the projections in images, as shown in (c). (b) computes the 4-RoSy field using QuadriFlow [21] and produces robust tangent principal directions, as shown in (d) as the projection in the image plane.

Figure 4. Local Canonical Frames Dataset. For each RGB frame, we render the corresponding tangent principal directions (X and Y) for each pixel. The ground truth normal can be directly computed as the cross product of the principal directions.

We store the computed local canonical frames on top of mesh vertices and render them to images after transforming them to the camera space. For each triangle to be rendered, we enumerate the 90N (N ∈ Z) degree rotations to the tangent principal directions of the last two vertices, so as to align them with the first vertex before the standard rasterization stage. This is to deal with the 4-way rotational ambiguities in the cross field. For each RGB image, we render and save the tangent principal directions as two images, as shown in figure 4 as X and Y. The ground truth normal can be directly computed as the cross product of the principal directions.

3.2. Projected Principal Directions

Since we aim to predict 3D principal tangent directions from their appearances into RGB images, we first derive the
projective geometry that relates them.

For a pixel \( p = (p_x,p_y) \) in the canonical camera coordinate system, its 3D position of the pixel can be represented as \( P = (p_xd,p_yd,d) \) where \( d \) is the depth value. Suppose the pixel has two tangent principal directions \( i \) and \( j \), and we want to analyze their projections. For \( i = (i_x,i_y,i_z) \), we can project a line segment \( l(P,\delta,i) \) that connects endpoints \( P \) and \( P + \delta \cdot i \) into the image as \( l_p(P,\delta,i) \), which is the offset from \( p \) to the projection of \( P + \delta i \):

\[
l_p(P,\delta,i) = \frac{P + \delta i - P}{|P + \delta i|_2} \cdot \delta = \frac{(i_x - p_xi_z, i_y - p_yi_z)}{d + \delta i_z} \tag{1}
\]

We find several ways to translate the projected line segment as a property of the pixel, as shown in equation 2,3,4. The most straightforward idea is to define the property as the projection of the unit 3D line segment from the pixel through the principal directions, represented as

\[
l_p(P,i) := l_p(P,1,i). \tag{2}
\]

This simple definition, however, requires a complex mathematics form including the depth value as a hidden information. Thus it could be hard to learn. Another property is the normalized projected principal direction, or

\[
l_p^w(P,i) := \frac{l_p(P,\delta,i)}{||l_p(P,\delta,i)||_2} = \frac{(i_x - p_xi_z, i_y - p_yi_z)}{||(i_x - p_xi_z, i_y - p_yi_z)||_2} \tag{3}
\]

This representation removes the influence of depth as the challenging hidden property. Since the projection usually aligns with the image gradients, it can be as easy as the task of predicting the normalized gradient for the neural network. However, though this is an easy task, the unit projected direction cannot determine the original 3D direction. As shown in figure 6(a), a 2D direction in an image is corresponding to a plane in the 3D world, in which any 3D direction could be a valid solution. Fortunately, we can simplify the definition as

\[
l_p^w(P,i) := (i_x - p_xi_z, i_y - p_yi_z). \tag{4}
\]

3.3. Joint Estimation

We could train a network to estimate the projected principal directions \( i_p = l_p^w(P,i) \) and \( j_p = l_p^w(P,j) \), and directly infer \( i \) and \( j \) according to equation 5 for canonical frames estimation. However, we find that this approach does not lead to a robust canonical frames. Therefore, we propose to jointly estimate the canonical frames as well as the projected tangent principal directions, and enforce their orthogonality and projection consistency with additional soft energy constraints. We expect that the extra constraints will provide a regularization that can help the network learn.

Our proposed solution is illustrated in figure 5. The neural network can be viewed as a black box function that predicts per-pixel features for the RGB image. Since the projected tangent principal directions relate to the pixel coordinate in the canonical camera, we feed the canonical pixel coordinate together with its RGB values into the network as the input. The network outputs a 13-dimensional vector includes two tangent principal directions \( i \) and \( j \), their 2D projections \( i_p \) and \( j_p \), and the surface normal \( n \).
We propose a set of energies so that projected tangent principal directions can assist the local principal axes estimation. The loss energy $E$ is a linear combination of five energy terms as shown in equation 6,

$$E = \lambda_L E_L + \lambda_P E_P + \lambda_N E_N + \lambda_C E_C + \lambda_O E_O$$

$$E_L = \min_{0 \leq k \leq 4} ||[i_p, j_p] - R_k([i_g, j_g])||_2$$

$$E_P = \min_{0 \leq k \leq 4} ||[i, j] - R_k([i_g, j_g])||_2$$

$$E_N = ||N - N^g||_2$$

$$E_C = ||l^*_p(i) - i_p||_2 + ||l^*_p(j) - j_p||_2$$

$$E_O = ||N - i \times j||_2^2$$

(6)

where $R_k([a, b]) = [-b, a]$ and $R_k = R_1 \circ R_{k-1}(k > 1)$.

Specifically, $E_L$ measures the distance between the predicted tangent principal directions and the ground truth in the 2D projected space. $R_k$ represents the 90k degree rotation around the normal axis. $E_L$ removes the rotational ambiguity by enumerating the possible 90k° rotations and measure the minimum L2 loss among them. Similarly, $E_P$ measures the minimum L2 loss of tangent principal directions in the 3D space, and $E_N$ measures the L2 loss of the surface normal estimation. In order to connect the tangent principal directions to their projections, we design $E_C$ to measure the consistency between the projected predicted directions ($l^*_p(i),l^*_p(j)$) and the predicted one ($i_p,j_p$) by the network. Finally, we also hope the influence can be propagated to the surface normal, so we add an orthogonality constraint $E_O$ to enforce that the surface normal is orthogonal to the tangent principal directions.

Since all the distances are roughly on the same scale, we set $\lambda_L = \lambda_P = \lambda_N = 1$ to balance the penalty for errors for different vectors. To enforce the system to predict orthogonal canonical frames with consistent 2D projection, we set $\lambda_C = \lambda_O = 5$ in our experiments to provide slightly stronger constraints between network predictions.

4. Evaluation

In this section, we describe a series of experiments to evaluate our method for local canonical frames estimation and do ablation studies using the ScanNet dataset [9]. Unless otherwise specified, we used the DORN architecture [12] as the backbone for the architecture in fig. 5, and we used equation 4 for the projected tangent principal directions, since they gave the best results (see below). The main conclusion of these tests is that jointly predicting the projected tangent directions and enforcing the consistency loss are major contributors to the success of local principal axes and surface normal estimation.

How well can canonical frames be estimated from RGB? Our first experiment simply investigates how well our algorithm can predict the canonical frames. Since this is a new task, there is no suitable comparison to prior work. However, we can still gain insight into the problem by comparing errors in predicted normals, principal tangent principal directions, and projected tangent principal directions. The results in table 1 show that prediction of projected tangent principal directions have least error, surface normals have most error, and tangent principal directions are in the middle. This suggests that predicting tangent directions is less error prone than normals, which should be expected since they largely align with textures and gradients in the input image (figure 7).

**Which frame directions are easiest to predict?** To further investigate the relative challenge of predicting different components of the local canonical frames, we perform experiments in which we separately train normals and tangent principal directions in 3D space with L2 losses and evaluate them with mean angle errors of their projections to three planes in camera space, as illustrated in figure 8. The prediction errors and their projected components, listed in table 2, suggest that the errors of the tangent principal directions are less than those of normals, and the projected errors
Does the method generalize to different networks? To study the generality of our approach, we tested it with different network architectures. Table 3 shows that our joint losses improve performance for all the tested networks including UNet [31], SkipNet [3], GeoNet [28] and DORN [12].

Which definition of projected directions is best? In equation 2-4, we propose three choices for projected tangent principal directions. We use UNet [31] to separately train and test them on ScanNet [9] as shown in Table 4. The mean angle error for equation 2 is the highest as a complex function related to the depth. The error for equation 4 is only slightly higher than that in equation 3, but equation 4 can explicitly guide the 3D directions with the consistency loss $E_C$. Therefore, we select equation 4 together with the canonical frames for joint estimation.

5. Applications

In this section, we investigate whether the estimation of local canonical frames is useful for applications. We first study surface normal estimation, a direct application of our method. In addition, we study how 3D canonical frames can be utilized for perspective invariant feature descriptors and augmented reality.

5.1. Surface Normal Estimation

Test on ScanNet We first compare the performance of our surface normal estimation with state-of-the-art methods on ScanNet [9]. We use our approach to train four networks and evaluate them according to ground truth provided by RGBD. Table 5 shows the results for all networks including UNet [31], SkipNet [3], GeoNet [28] and DORN [12]. With the assistance of the projected tangent principal directions, the normal prediction is better for all architectures.

Figure 13 visualizes the normals predicted using DORN with and without our method. With our approach, the errors are smaller especially at object boundaries, possibly because of the additional supervision given by the projected tangent principal directions.

| Method     | UNet | SkipNet | GeoNet | DORN    |
|------------|------|---------|--------|---------|
| $E_N$      | 21.08| 20.36   | 19.77  | 16.42   |
| $E_N,E_P$  | 20.04| 20.45   | 19.64  | 16.29   |
| $E_N,E_P,E_L$ | 20.62| 19.47   | 19.26  | 15.45   |
| $E_N,E_P,E_L,E_O$ | 19.79| 19.84   | 19.02  | 15.31   |
| All Losses | **19.68** | **19.39** | **18.96** | **15.28** |

Table 3. We test mean average angle errors for surface normal predictions with different combination of loss terms on ScanNet. $E_L$ and $E_C$ have major contributions to the improvement, suggesting the importance of the projected principal directions.

on the image plane are smaller than those on the other two planes for tangent principal directions. This again suggests that the network can predict tangent principal directions better than surface normals, especially for the components projected into the image plane. Interestingly, the projected errors for the normal in the image plane is the largest, which might be because the network learns tangent principal directions in the latent space and propagates the errors from XZ and YZ planes to the image plane by the cross product.

How does each loss contributes to the estimation? We next study how our proposed consistency losses influence the learning process. In Table 3, we present the testing mean average angle for surface normals w/o. certain parts of losses during training on ScanNet. We note that by directly predicting all $E_N$ and $E_P$ together, there is already an improvement. The reason could be that the correlation between predicted principal directions and the 3D frames are automatically learned from the data distribution. However, the improvement is minor without predicting the projected principal directions with $E_L$. With orthogonal or consistency constraints, the performance can be further improved and achieve maximum with both.

Does the method generalize to different networks? To study the generality of our approach, we tested it with different network architectures. Table 3 shows that our joint losses improve performance for all the tested networks including UNet [31], SkipNet [3], GeoNet [28] and DORN [12].

Which definition of projected directions is best? In equation 2-4, we propose three choices for projected tangent principal directions. We use UNet [31] to separately train and test them on ScanNet [9] as shown in Table 4. The mean angle error for equation 2 is the highest as a complex function related to the depth. The error for equation 4 is only slightly higher than that in equation 3, but equation 4 can explicitly guide the 3D directions with the consistency loss $E_C$. Therefore, we select equation 4 together with the canonical frames for joint estimation.

5. Applications

In this section, we investigate whether the estimation of local canonical frames is useful for applications. We first study surface normal estimation, a direct application of our method. In addition, we study how 3D canonical frames can be utilized for perspective invariant feature descriptors and augmented reality.

5.1. Surface Normal Estimation

Test on ScanNet We first compare the performance of our surface normal estimation with state-of-the-art methods on ScanNet [9]. We use our approach to train four networks and evaluate them according to ground truth provided by RGBD. Table 8 shows the results for all networks including UNet [31], SkipNet [3], GeoNet [28] and DORN [12]. With the assistance of the projected tangent principal directions, the normal prediction is better for all architectures.

Figure 13 visualizes the normals predicted using DORN with and without our method. With our approach, the errors are smaller especially at object boundaries, possibly because of the additional supervision given by the projected tangent principal directions.

| Method     | mean | median | rmse | 11.25° | 22.5° | 30° |
|------------|------|--------|------|--------|-------|-----|
| UNet       | 11.13| 7.63   | 15.00| 65.1   | 86.2  | 92.5|
| SkipNet    | **7.35** | **4.38** | **10.94** | **81.2** | **93.6** | **96.7** |
| SkipNet-Ours | 7.56 | 4.46   | 11.36| 79.8   | 93.0  | 96.3|

Table 4. Testing mean average error of different choices for projected tangent principal directions on ScanNet dataset.

| Method     | mean | median | rmse | 11.25° | 22.5° | 30° |
|------------|------|--------|------|--------|-------|-----|
| ScanNet    | 21.08| 14.21  | 28.55| 40.8   | 66.9  | 76.3|
| UNet       | 19.68| 12.43  | 27.58| 46.1   | 70.6  | 78.8|
| SkipNet    | **20.36** | **13.74** | **28.63** | **45.4** | **68.2** | **77.4** |
| SkipNet-Ours | 19.39 | 10.85  | 27.52| 53.2   | 72.7  | 79.3|

Table 5. Evaluation on Surface Normal Predictions. We train and test our algorithm with different network architectures on the ScanNet [9] dataset. Assisted by our joint loss, the performances of all networks are improved.
Figure 9. Visual comparison of the results. With our joint loss, the predicted surface normals produce less errors and more details.

| Dataset   | Loss Type | mean | median | rmse | 11.25° | 22.5° | 30° |
|-----------|-----------|------|--------|------|--------|-------|-----|
|           | GeoNet-origin | 19.0  | 11.8   | 26.9 | 48.4   | 71.5  | 79.5|
| ScanNet   | mean      | 23.46 | 15.45  | 30.60| 47.0   | 62.0  | 72.7|
|           | median    | 22.09 | 14.25  | 28.33| 46.3   | 67.4  | 76.0|
|           | rmse      | 21.75 | 13.42  | 28.19| 47.9   | 68.0  | 76.4|
|           | GeoNet    | 19.12 | 11.60  | 27.06| 49.0   | 70.6  | 78.5|
|           | GeoNet-Ours | 18.63 | 11.16  | 26.61| 50.2   | 71.6  | 79.5|

Table 6. Normal prediction on NYUv2 [11]. GeoNet-origin trained and tested on NYUv2 [28]. DORN-Ours trained on ScanNet performs best among all.

Test on NYUv2 We test different versions of our network on NYUv2 [11] as a standard evaluation dataset. Since NYUv2 does not provide reconstructed 3D meshes, we cannot get ground truth 3D frames. Therefore, we train the network on ScanNet datasets and directly test on NYUv2, as shown in Table 6. Note that GeoNet-origin [28] is specifically trained and tested on NYUv2 and is the current state-of-the-art method on normal estimation for that dataset. Other rows are networks trained with and without our joint losses on ScanNet and tested on NYUv2.

Although GeoNet performs worse than GeoNet-origin by training only on ScanNet without fine-tuning, we still achieve better performance with the DORN [12] architecture and our loss (DORN-Ours). Moreover, all networks show better performance with our loss, implying a robust advantage of our joint estimation.

5.2. Keypoint Matching

Predicting local transformations is important for keypoint feature matching [26, 4, 40, 15, 51, 36, 49]. For example, SIFT [26] estimates scale and camera-plane rotations to provide invariance to those transformations. Since our network estimates a full local 3D canonical frames, we can additionally estimate a projective warp. Specifically, predicting the pairs of projected tangent principal directions (in equation 4) for pixel $p$ as $i_p$ and $j_p$, the local patch $P$ is warped to $P^*$ as shown in equation 7.

$$P^*(x) = P([i_p, j_p]x)$$  (7)

To investigate this feature, we performed a simple experiment with SIFT [26]. We augmented the standard SIFT descriptor computation to account for perspective warps implied by our predicted canonical frames. Specifically, we detect keypoints using SIFT [26], and extract the SIFT descriptors on the warped patch using our estimated local projected tangent principal directions.

To evaluate our modified descriptor, we compare it with other methods on the DTU dataset [1], where scenes are captured with different lighting and viewpoints. We visualize the correct matching produced by SIFT with and without our local image warping in figure 11. As a result, the local image warping reduces the perspective distortions and produce more correct matches. We also test the matching score as “the ratio of ground truth correspondences that can be recovered by the whole pipeline over the number of features proposed by the pipeline in the shared viewpoint region” [49]. As shown in table 7, SIFT [26]
Table 7. Matching score of descriptors on the DTU dataset.

| Method        | SURF [4] | ORB [32] | Daisy [40] | BRISK [24] | VGG [22] | MatchNet [18] | DeepDesc [36] | PN-Net [2] | SIFT [26] | ASIFT [50] | LIFT [49] | SIFT+Ours |
|---------------|----------|----------|------------|------------|----------|---------------|---------------|------------|----------|-----------|----------|----------|
| Score         | .224     | .127     | .262       | .193       | .271     | .198          | .257          | .267       | .265     | .317      | .335     |

outperforms most methods. Since our method additionally reduces the perspective effects using the projected tangent principal directions, we can further improve the SIFT performance. Note that ASIFT [50] also perceives the limitation of SIFT [26] to different viewpoints, and extracts keypoints from the image with various affine transforms. Therefore, they usually provide many more correct matching but also more outliers. That is why the matching score produced by ASIFT [50] is slightly lower than SIFT [26]. However, it sometimes shows better robustness assisted by geometric filters in certain applications.

5.3. Augmented Reality

A particularly compelling application of predicting 3D surface frames is augmented reality – i.e., it enables adding new elements to a scene with appropriate 3D orientations.

Decal Attachment As a simple example, we investigate warping virtual decals added to RGB images based on the estimated 3D frame (first two rows of figure 12). In our experiment, we ask the user to select one pixel in an RGB image to indicate the center point for the decal on a surface. If we assume the surface is planar, we can compute the homography transformation required to align the decal with the scene geometry. Suppose the selected pixel is \( p \) with two estimated principal directions \( i \) and \( j \) and depth \( d \). Then, the center of the pattern \( (x_c, y_c) \) is located at \( K^{-1}p \cdot d \) where \( K \) is the camera intrinsics. We additionally suppose that the target distance of neighboring pixels of the pattern attached to the scene is \( \delta \cdot d \). Then, for pixel \( (x, y) \) in the pattern, the homogeneous coordinate in the scene is

\[
P(x, y) = K^{-1}p \cdot d + i \cdot (x - x_c) \delta d + j \cdot (y - y_c) \delta d
\]

Therefore, the homography transform can be inferred as

\[
H = K[\delta i, \delta j, K^{-1}p - \delta(x_c i + y_j)]
\]

Here, \( \delta \) represents the relative scale of the pattern to the depth of the pixel, which can be controlled by the user. Beyond this point, our local frame even enables deformable pattern attachment on curved surfaces. Similarly, the homogeneous coordinate of any pixel \( x_i \) can be computed as

\[
P(x_i) = p + \delta K \cdot \int_{x_c}^{x_i} [i(P(x)), j(P(x))] \, dx
\]

We use the simple explicit Euler method to evolve \( P(x) \), where the path of the integration starts from the center, and

follows the order guided by the breadth first search, where the expansion is from one pixel to those among its four neighbors which are not yet visited. Several examples of deformable attachment is shown in figure 12. The user can control \( \delta \) to specify the size of the attached patterns.

Object Placement We can also use the local 3D frame defined by predicted principal axes to render 3D objects into RGB images, as shown in the last two rows of figure 12. For this application, predicting the full 3D orientation of the scene geometry is critical, so that objects can be planes not only in accordance with the surface normal, but also in the appropriate rotation around the normal (e.g., so that the front is facing the right way). For example, the stuffed animals in the bottom left of figure 12 would appear unnatural if they were facing the wall. This could also ease mixed reality data augmentation for vision tasks, where existing methods require the depth image for plane detection [42].

6. Conclusion

We propose the novel problem of densely estimating local 3D canonical frames from a single RGB image. We formulate the problem as a joint estimation of surface normals, canonical tangent directions, and projected tangent directions. We find this approach leads to superior performance as compared to previous work on normal estimation and other tasks. Further study is warranted to investigate what other geometric properties can be predicted from RGB using similar methods and how they can be used in other applications.

Supplemental

A. Implementation Details

Our best-performing implementation is based on the DORN architecture [12], which was originally proposed for depth estimation on the NYUv2 dataset. We adopt the original parameters, except that we output 13 dimensions at the final layer and use our loss to train the network. During our experiments, the input and output image resolution is 320x240. We use the fixed learning rate as 1e-5.

B. Timing

We render one keyframe for every ten frames for ScanNet [9] dataset, which yields about 200,000 training samples. We take 4.8 hours to train DORN [12] and our loss for one epoch and report the performance after training 9 epochs. During testing, we use 0.0375 second to process each image.

C. Surface Normal Estimation

Comparison with the state-of-the-art We show results for surface normal estimation using ScanNet for training and testing in section 5.1 of the main paper. In this section, we do the same using the SunCG dataset [38]. Specifically, we use our approach to train four networks using the SUNCG training set and evaluate them on the SUNCG test set. Table 8 shows the results for UNet [31], SkipNet [3], GeoNet [28] and DORN [12]. With the assistance of the projected tangent principal directions, the normal predictions is improved in every case.

| Network   | mean  | median | rmse  | 11.25° | 22.5° | 30°  |
|-----------|-------|--------|-------|--------|-------|------|
| SunCG     |       |        |       |        |       |      |
| UNet      | 14.88 | 6.20   | 24.94 | 64.4   | 78.6  | 83.9 |
| UNet-Ours | 13.25 | 4.64   | 23.73 | 69.8   | 81.6  | 86.1 |
| SkipNet   | 13.38 | 3.97   | 24.54 | 70.2   | 80.3  | 85.1 |
| SkipNet-Ours | 12.82 | 3.87   | 23.69 | 71.0   | 80.2  | 86.1 |
| GeoNet    | 13.14 | 3.56   | 23.54 | 70.6   | 80.7  | 86.0 |
| GeoNet-Ours | 12.68 | 3.60   | 22.73 | 71.2   | 81.3  | 86.6 |
| DORN      | 12.90 | 3.36   | 24.12 | 71.3   | 81.3  | 85.3 |
| DORN-Ours | 12.38 | 3.33   | 23.34 | 72.3   | 82.3  | 86.3 |

Table 8. Evaluation on Surface Normal Predictions. We train and test our algorithm with different network architectures on the SunCG [9]. Assisted by our joint loss, the performances of all networks are improved.

D. Visualization

Visualization of surface normals. Figure 13 visualizes surface normal predictions using the best model with and without our approach. With our approach, the errors are smaller especially at object boundaries, possibly because of the additional supervision given by the projected tangent principal directions. Overall, there is a noticeable improvement, especially for small objects.

Visualization of tangent principal directions. Figure 14 shows more visualizations of projected tangent principal directions predicted with our model trained on ScanNet [9] using Dorn [12] without joint loss. You can see that the direction fields are qualitatively similar to the ground truth and aligned with the principal directions of the surfaces.
Figure 14. Visualization of the projected tangent principal directions. The visualization shows similar direction field compared to the ground truth, and is consistent with human intuition.

Figure 15. Visualization of the feature matching using SIFT and SIFT with our perspective rectification. We produce more correct matching than SIFT does.
Visualization of augmented reality results. Figure 16 shows more visualizations with comparisons between SIFT and SIFT with our perspective rectification on the DTU dataset [1]. You can see that our method produces more correct matches than the baseline SIFT method.

Visualization of feature matching. Figure 15 shows more visualizations with comparisons between SIFT and SIFT with our perspective rectification on the DTU dataset [1]. You can see that our method produces more correct matches than the baseline SIFT method.

Visualization of augmented reality results. Figure 16 shows more examples of new elements inserted into images using the tangent principal directions predicted with our model. You can see that the perspectives are locally consistent with the canonical frames of the geometry.
