**ABSTRACT**

We have observed CH absorption lines \((J = 3/2, N = 1 \leftrightarrow J = 1/2, N = 1)\) against the continuum source Sgr B2(M) using the *Herschel*/HIFI instrument. With the high spectral resolution and wide velocity coverage provided by HIFI, 31 CH absorption features with different radial velocities and line widths are detected and identified. The narrower line width and lower column density clouds show “spiral arm” cloud characteristics, while the absorption component with the broadest line width and highest column density corresponds to the gas from the Sgr B2 envelope. The observations show that each “spiral arm” harbors multiple velocity components, indicating that the clouds are not uniform and that they have internal structure. This line-of-sight through almost the entire Galaxy offers unique possibilities to study the basic chemistry of simple molecules in diffuse clouds, as a variety of different cloud classes are sampled simultaneously. We find that the linear relationship between CH and H\(_2\) column densities found at lower \(A_v\) by UV observations does not continue into the range of higher visual extinction. There, the curve flattens, which probably means that CH is depleted in the denser cores of these clouds.

1. **Introduction**

While physical and chemical conditions of molecular clouds associated with star-forming regions are widely explored by observing various molecular species, much less is known about the chemistry of the bulk of molecular clouds in the spiral arms of our Galaxy. These have mostly been studied only in the CO molecule, with some exceptions. These exceptions consist of clouds that happen to lie along the line-of-sight to a bright Galactic or extragalactic continuum source, and can be observed in absorption. Examples for spiral arm clouds probed by gas absorption are the Sgr B2, W-49, W51, and Cas A millimeter continuum sources, where the chemistry was studied mostly through low-energy lines of molecular species (e.g., Greaves & Williams 1994; Greaves & Nyman 1996; Gerin et al. 2010; Menten et al. 2010; Lis et al. 2010; Schilke et al. 2010; Tieftrunk et al. 1994; Wyrowski et al. 2010). Liszt & Lucas (2002) also made important contributions to this field through observations of absorption line clouds against quasars. The observations show that most of the absorption signal arises from diffuse/translucent clouds with low gas density and excitation temperature, suggesting that the ambient ultraviolet field plays a prominent role in determining the chemistry (Liszt 2009). The very light hydride radical CH (methylidyne) has been observed in diffuse clouds in front of bright OB stars at optical wavelengths and in dark clouds at radio wavelengths, showing that CH column density is linearly correlated with the optical extinction \((A_V)\) for \(A_v\) less than 4 m (e.g., Lang & Wilson 1978; Federman 1982; Sheffer et al. 2008). Observations and chemical models also indicate that CH abundance is lower by a factor of 100–1000 in dense clouds and is mainly located in the surface layers of dense clouds (Viala et al. 1979; de Jong et al. 1979; Boland & Dalgarno 1980; Goicoechea et al. 2004; Polehampton et al. 2007) or low column density clouds (Mattila 1986; Magnani et al. 2005).
The prominent Sagittarius B2 star-forming region is very close (~130 pc) to the Galactic center and at a distance of ~8 kpc from the Sun (Reid et al. 2009). The dense cores contained in it, Sgr B2(N) and Sgr B2(M), are well-studied massive star-forming regions. Sgr B2(M) is stronger at submm wavelengths and also less contaminated by emission lines than its neighbor Sgr B2(N) (Goldsmith et al. 1990; Nummelin et al. 1998), making it the target of choice for absorption studies. HIFI, the Heterodyne Instrument for the Far-Infrared (de Graauw et al. 2010) onboard the Herschel Space Observatory (Pilbratt et al. 2010) is an ideal instrument for making such observations. In this Letter, we present high spectral-resolution HIFI observations of CH towards Sgr B2(M).

2. Observations

A full spectral scan of Sgr B2(M) in the HIFI band 1a, covering a frequency range from 479.6 to 560.3 GHz was carried out on March 1, 2010, and was pointed at α(J2000) = 17h47m20.2s and δ(J2000) = −28°23′05.0″, using the dual beam switch (DBS) mode as part of the guaranteed time key program HEXOS: Herschel/HIFI observations of EXtra-Ordinary Sources: The Orion and Sagittarius B2 star forming regions (Bergin et al. 2010). The DBS reference beams lie approximately 3° east and west (i.e. perpendicular to the roughly north-south elongation of Sgr B2). The 1.1 MHz spectral resolution of the wide band spectrometer (WBS) corresponds to a velocity resolution of ~0.6 km s⁻¹ over a 4 GHz IF bandwidth. The data have been processed through the standard pipeline released with version 2.9 of HIPE (Ott et al. 2010), including removal of the standing waves, and subsequently exported to FITS format. The double-sideband (DSB) spectra were deconvolved into single-sideband spectra, including the continuum (Comito & Schilke 2002) using the IRAM GILDAS package. The systematic velocity of the source was corrected to the local stand of rest (LSR) frame. Both H and V polarization data were obtained. The data presented here are averages of the two polarizations with equal weighting. The HIFI beam size at 532 GHz is ~37″, with a main beam efficiency of 0.69.

3. Results

The low-frequency radio transitions of CH are between Λ-type doublet states, while spin-rotational as well as rotational transitions fall in the far-infrared and submillimeter bands (Brown & Evison 1983). Early observations mainly focused on the low-frequency radio and far-infrared lines, the latter with relative low spectral resolution. The lowest spin-rotational transitions of CH at 532.8 and 536.8 GHz were measured in the laboratory by Amano (2000), thus lying in a range of strong atmospheric water absorption, which makes their observation with ground-based telescope impossible. The level populations for the 532.8 and 536.8 GHz transitions are expected to have a low excitation temperature in most clouds, with the possible exception of the Sgr B2 envelope, and thus provide a good measure of the total column density from absorption measurement.

Six hyperfine components of CH in the ground electronic state ($X ^{1}Σ^ {−}$), $J = 3/2, N = 1 ← J = 1/2, N = 1$ near 532.8 (1+ ← 1−, 2+ ← 1−, and 1+ ← 0−), and 536.8 GHz (2− ← 1+), and 1− ← 1+, and 1− ← 0+) are included in the HIFI band 1 observations of Sgr B2(M). The CH spectra near 532.8 and 536.8 GHz obtained with HIFI are presented in Fig. 1, with multiple velocity components seen in absorption. The observations of CH at $J = 3/2, N = 2 ← J = 1/2, N = 2$ in far-infrared (~2010 GHz) with a velocity resolution of >30 km s⁻¹ towards Sgr B2 using the ISO and the Kuiper Airborne Observatory (KAO) 91.4 cm telescope showed absorption centered on 65 km s⁻¹ with an unusually large line width of ~200 km s⁻¹ (Stacey et al. 1987; Goicoechea et al. 2004; Polehampton et al. 2007), which samples the gas from both the Galactic center and spiral arm clouds along the light of sight. The HIFI CH spectra are spectrally resolved into multiple velocity components with different line intensities and widths. The strong CH absorption at ~64 km s⁻¹ with the largest line width clearly corresponds to the envelope of the Sgr B2(M) cloud. In addition to the Sgr B2(M) absorption cloud, the radial velocities of the other absorption components are consistent with those of the spiral arm clouds and kinematic features associated with the Galactic center (e.g., Greaves & Williams 1994; Menten et al. 2010). HIFI observations of H₂O and H₂O in the spiral arm clouds against the Sgr B2(M) continuum show somewhat different spectral profiles than CH (Schilke et al. 2010; Lis et al. 2010). Probably each molecular species samples slightly different regions within various clouds along the line of sight.

Absorption-line column densities can be calculated from the observed line-to-continuum ratio by Gaussian fitting to the lines, if the absorption spectrum comes from a single molecular species without hyperfine components, as long as the spectrum is not contaminated by emission from other species. We have not identified any strong interfering lines in the velocity range of the 532.8 and 536.8 GHz CH absorption. However, the hyperfine structure of CH makes it difficult to uniquely assign the absorption to distinct velocity components and calculate their column densities. Taking the hyperfine components and contamination from other species into account, and using the LTE approximation, we modeled the CH spectra by employing XCLASS³ and the automated fitting routine provided by MAGIX². We adopted 2.73 K as rotation temperature for all absorption components, which is questionable only for the Sgr B2 component itself, since the envelope is hot and dense enough to excite CH. A reliable estimate of the CH column density and abundance in this component has to await detailed radiative transfer modeling. Keeping the velocity offsets fixed, we used 31 absorption components and 1 emission component, as for c-C₃H₂ and H¹³CO⁺ cases (Menten et al. 2010) for the CH model fitting. We assume that the opacity at any velocity is a sum of contributions from all CH hyperfine components and that the absorbing layers cover the continuum completely. The best fits to the spectra along with the line opacity as a function of velocity are shown in Fig. 1. The column densities and line widths of the 31 absorption components of the best-fit model are given in Table 1. Based on the results of Menten et al. (2010) and Greaves & Williams (1994), the corresponding name of the spiral arm clouds for each velocity component is also given in Table 1.

The column densities range from $2.3 \times 10^{13}$ to $5.2 \times 10^{14}$ cm⁻². The Sgr B2 cloud (~64 km s⁻¹) has the largest line width and highest column density. Most of the components have column densities of a few times $10^{13}$ cm⁻². The mean column density is $5.4 \times 10^{13}$ cm⁻², excluding Sgr B2(M). This is similar to the Herschel/HIFI observations of CH towards the

¹ We made use of the myXCLASS program (https://www.astro.uni-koeln.de/projects/schilke/XCLASS), which accesses the CDMS (Müller et al. 2001; Müller et al. 2005; http://www.cdms.de) and JPL (Pickett et al. 1998; http://spec.jpl.nasa.gov) molecular data bases.
² https://www.astro.uni-koeln.de/projects/schilke/MAGIX
massive star-forming region NGC 6334 (Van der Wiel et al. 2010), in which the NGC 6334 envelope has the highest column density of $1.7 \times 10^{14}$ cm$^{-2}$, while foreground clouds have a column density of several $10^{13}$ cm$^{-2}$. The CH column densities in our observations are similar to those in diffuse clouds and dark nebulae (e.g., Federman 1982; Liszt & Lucas 2002; Mattila 1986). Each spiral arm cloud harbors several velocity components with different line widths and column densities. The velocity structure in each spiral arm cloud suggests that the clouds are not uniform and have internal structure.

### 4. Discussion

For absorption lines, both the observed antenna temperature and column density of a specific molecule are related to optical depth and excitation temperature. The optical depths in this work are derived from the observed line-to-continuum ratio, therefore the uncertainties due to the absolute flux calibration will not affect the values of the optical depth. The brightness temperature of the background continuum is determined from the baseline offset, which is fairly reliable for HIFI (Bergin et al. 2010). The only assumption is that the absorption completely covers the continuum. The spiral-arm cloud sizes are approximately 3 pc corresponding to 150$''$ at a distance of 4 kpc (Greaves & Williams 1994), which is more than the size of the Sgr B2(M) continuum. The same set of parameters in the LTE model fits both the spectral features near 532.8 and 536.8 GHz well. The typical optical depths are 0.5, while the largest optical depth is ~1 at 64 km s$^{-1}$

**Notes.**

(a) The H$_2$ column densities are decoded from HCO$^+$ column densities (Menten et al. 2010). (b) Sgr B2(M); (c) Scutum arm; (d) Sagittarius arm; (e) Galactic center; (f) Norma arm (3 and 4 kpc arms).

(see Fig. 1). Thus, our LTE fitting gives a reliable assessment of the column densities.

Determining of the fractional abundance of a molecule relative to H$_2$ requires the column densities of both the molecules in question and H$_2$. A direct measurement of H$_2$ column density is difficult. HCO$^+$ has been shown to have an approximately constant abundance relative to H$_2$ in a wide range of environments, including diffuse clouds, low- and high-mass star-forming regions, and compact extragalactic continuum sources (e.g., Greaves & Nyman 1996; Lucas & Liszt 1996; van Dishoeck et al. 1993); therefore, HCO$^+$ can be taken as a proxy of H$_2$. However, HCO$^+$ itself is optically thick in most velocity components. Following Menten et al. (2010), we use the optically thin H$^{13}$CO$^+$ column densities from Table 4 of Menten et al. (2010) to determine the H$_2$ column density and fractional abundance of CH relative to H$_2$ for each velocity component. This procedures takes measured $^{12}$C/$^{13}$C ratios in the various spiral-arm clouds into account and assumes a constant HCO$^+$/H$_2$ ratio of $5 \times 10^{-7}$. The fractional abundances of CH relative to H$_2$ are listed in the fifth column of Table 2. The derived H$_2$ column densities range from $1 \times 10^{21}$ to $3 \times 10^{22}$ cm$^{-2}$ with a total...
Figure 2 presents the relationship between the CH and H$_2$ column densities. A least-squares fit (excluding the Sgr B2(M) cloud with a value of $9.6 \times 10^{-10}$ because the excitation there is not straightforward).

Figure 2 shows the correlation of column densities of CH and H$_2$ in a log-log plot. H$_2$ column densities are derived from H$^{13}$CO$^+$. The green line shows the slope of 0.97 fitted to the data, indicating a least-squares fit to the data. The red line shows the slope of 1, which is consistent with the predictions of both turbulent dissipation and turbulence dominated chemistry, and distinguishes PDR and TDR models.

Acknowledgements: HIFI has been designed and built by a consortium of institutes and university departments from across Europe, Canada, and the United States under the leadership of SRON Netherlands Institute for Space Research, Groningen, The Netherlands, and with major contributions from Germany, France, and the US. Consortium members are: Canada: CSA, U.Waterloo; France: CESR, LAB, LERMA, IRAM; Germany: KOSMA, MPIfR, MPS; Ireland: NUI Maynooth; Italy: ASI, IFSI-INAF, Osservatorio Astrofisico di Arcetri- INAF; Netherlands: SRON, TUD; Poland: CAMK, CBK; Spain: Observatorio Astronómico Nacional (IGN), Centro de Astrobiología (CSIC-INTA). Sweden: Chalmers University of Technology – MC2, RSS & GARD; Onsala Space Observatory; Swedish National Space Board. Stockholm University – Stockholm Observatory; Switzerland: ETH Zurich, FHNW; USA: Caltech, JPL, NHSC.
