Abstract

A new Approximate Bayesian Computation (ABC) algorithm for Bayesian updating of model parameters is proposed in this paper, which combines the ABC principles with the technique of Subset Simulation for efficient rare-event simulation, first developed in S.K. Au and J.L. Beck \cite{Au2011}. It has been named ABC-SubSim. The idea is to choose the nested decreasing sequence of regions in Subset Simulation as the regions that correspond to increasingly closer approximations of the actual data vector in observation space. The efficiency of the algorithm is demonstrated in two examples that illustrate some of the challenges faced in real-world applications of ABC. We show that the proposed algorithm outperforms other recent sequential ABC algorithms in terms of computational efficiency while achieving the same, or better, measure of accuracy in the posterior distribution. We also show that ABC-SubSim readily provides an estimate of the evidence (marginal likelihood) for posterior model class assessment, as a by-product.

Keywords: Approximate Bayesian computation, Subset Simulation, Bayesian inverse problem

1. Introduction

The main goal of Bayesian statistics is to update a priori information about the parameter of interest $\theta \in \Theta \subset \mathbb{R}^d$ for a parameterized model class $M$, based on the information contained in a set of data which we express as a vector $y \in D \subset \mathbb{R}^l$, where $D$ is the observation space, the region in $\mathbb{R}^l$ of all possible observational outcomes according to the model class. As a part of the model class $M$, we choose a prior probability density function (PDF) $p(\theta|M)$ over the parameter space and we also derive $p(y|\theta,M)$, the likelihood function of $\theta$, from the stochastic forward model $p(x|\theta,M)$ of the model class $M$ \cite{Beck2002a}. Bayes’ Theorem then yields the posterior PDF $p(\theta|y,M)$ of the model specified by $\theta$ as follows:

\begin{equation}
\frac{p(\theta|M)p(y|\theta,M)}{\int_M p(\theta|M)p(y|\theta,M)d\theta} \propto p(\theta|M)p(y|\theta,M) \tag{1}
\end{equation}

However, evaluation of the normalizing integral in the denominator is usually intractable except in some special cases. Also, there are situations where Bayesian analysis is conducted with a likelihood function that is not completely known or it is difficult to obtain, perhaps because it requires the evaluation of an intractable multi-dimensional integral over a latent vector, such as in hidden Markov models or dynamic state-space models, or because the normalization in the likelihood over the observation space $D$ involves an intractable integral parameterized by $\theta$. Approximate Bayesian Computation (ABC) algorithms were conceived with the aim of evaluating the posterior density in those cases where the likelihood function is intractable.
although it also avoids the problem of the intractable integral in Equation \( 1 \). In the literature, these classes of algorithms are also called likelihood-free computation algorithms, which refers to their main aim of circumventing the explicit evaluation of the likelihood by using a simulation-based approach. In this introductory section, we briefly summarize the body of ABC literature with a brief description of the main concepts and algorithms that we will need in the subsequent sections.

Let \( x \in \mathcal{D} \subset \mathbb{R}^d \) denote a simulated dataset from \( p(\cdot|\theta, \mathcal{M}) \), the forward model of model class \( \mathcal{M} \). An ABC algorithm aims at evaluating the posterior \( p(\theta|y, \mathcal{M}) \propto p(y|\theta, \mathcal{M})p(\theta|\mathcal{M}) \) by applying Bayes’ Theorem to the pair \((\theta, x)\):

\[
p(\theta, x|y) \propto p(y|x, \theta)p(x|\theta)p(\theta)
\]

In the last equation, the conditioning on model class \( \mathcal{M} \) has been omitted for clarity, given that the theory is valid for any specific model class. The function \( p(y|x, \theta) \) gives higher weights for the posterior in those regions where \( x \) is close to \( y \). The basic form of the algorithm to sample from the posterior given by Equation \( 2 \) is a rejection algorithm that consists of generating jointly \( \theta \sim p(\theta) \) and \( x \sim p(x|\theta) \) and accepting them conditional on fulfilling the equality \( x = y \). Of course, obtaining sample \( x = y \) is unlikely in most applications, and it is only feasible if \( \mathcal{D} \) consists of a finite set of values rather than a region in \( \mathbb{R}^d \). Hence two main approximations have been conceived in ABC theory to address this difficulty \( 4 \): a) replace the equality \( x = y \) by the approximation \( x \approx y \) and introduce a tolerance parameter \( \epsilon \) that accounts for how close they are through some type of metric \( \rho \); and b) introduce a low-dimensional vector of summary statistics \( \eta(\cdot) \) that permits a comparison of the closeness of \( x \) and \( y \) in a weak manner. Through this approach, the posterior \( p(\theta, x|y) \) in Equation \( 2 \) is approximated by \( p_{\epsilon}(\theta, x|y) \), which assigns higher probability density to those values of \( (\theta, x) \in \Theta \times \mathcal{D} \) that satisfy the condition \( \rho(\eta(x), \eta(y)) \leq \epsilon \).

The standard version of the ABC algorithm takes the approximate likelihood \( P_{\epsilon}(y|\theta, x) = P(x \in \mathcal{N}_{\epsilon}(y)|x) \), where \( \mathcal{N}_{\epsilon}(y) = \{ x \in \mathcal{D} : \rho(\eta(x), \eta(y)) \leq \epsilon \} \). From Bayes’ Theorem, the approximate posterior \( p_{\epsilon}(\theta, x|y) = p(\theta, x|x \in \mathcal{N}_{\epsilon}(y)) \) is given by:

\[
p_{\epsilon}(\theta, x|y) \propto P(x \in \mathcal{N}_{\epsilon}(y)|x)p(x|\theta)p(\theta)
\]

where \( P(x \in \mathcal{N}_{\epsilon}(y)|x) = I_{\mathcal{N}_{\epsilon}(y)}(x) \), an indicator function for the set \( \mathcal{N}_{\epsilon}(y) \) that assigns a value of 1 when \( \rho(\eta(x), \eta(y)) \leq \epsilon \) and 0 otherwise. So the output of the ABC algorithm corresponds to samples from the joint probability density function:

\[
p_{\epsilon}(\theta, x|y) \propto p(x|\theta)p(\theta)I_{\mathcal{N}_{\epsilon}(y)}(x)
\]

with ultimate interest typically being in the marginal approximate posterior:

\[
p_{\epsilon}(\theta|y) \propto p(\theta)\int_{\mathcal{D}} p(x|\theta)I_{\mathcal{N}_{\epsilon}(y)}(x)dx = P(x \in \mathcal{N}_{\epsilon}(y)|\theta)p(\theta)
\]

This integration need not be done explicitly since samples from this marginal PDF are obtained by taking the \( \theta \) component of samples from the joint PDF in Equation \( 4 \) and \( 5 \). Notice that the quality of the posterior approximation in Equations \( 4 \) and \( 5 \) depends on a suitable selection of the metric \( \rho \), the tolerance parameter \( \epsilon \) and, of special importance, the summary statistic \( \eta(\cdot) \). A pseudocode to generate \( N \) samples by the standard version of ABC algorithm is given in Algorithm \( 1 \).

The choice of tolerance parameter \( \epsilon \) is basically a matter of the amount of computational effort that the user wishes to expend but a possible guiding principle is described later at the end of Section 3.1.2. For \( \epsilon \) sufficiently small (\( \epsilon \to 0 \)), \( \eta(x) \to \eta(y) \), and so all accepted samples corresponding to Equation \( 5 \) come from the closest approximation to the required posterior density \( p(\theta|y) \), where the exactness is achieved when \( \eta(\cdot) \) is a sufficient statistic. This desirable fact is at the expense of a high computational effort (usually prohibitive) to get \( \eta(x) = \eta(y) \) under the model \( p(x|\theta) \). On the contrary, as \( \epsilon \to \infty \), all accepted observations come from the prior. So, the choice of \( \epsilon \) reflects a trade-off between computability and accuracy.

\[\text{In what follows, we use } P(\cdot) \text{ to denote probability whereas a PDF is expressed as } p(\cdot).\]
Several computational improvements have been proposed addressing this trade-off. In those cases where the probability content of the posterior is concentrated over a small region in relation to a diffuse prior, the use of Markov Chain Monte Carlo methods (MCMC) has been demonstrated to be efficient. In fact, the use of a proposal PDF over the parameter space allows a new parameter to be proposed based on a previous accepted one, targeting the stationary distribution. The resulting algorithm, commonly called ABC-MCMC, is similar to the standard one with the main exception being the acceptance probability, which in this case is influenced by the MCMC acceptance probability as follows:

Algorithm 1 Standard ABC

\begin{algorithm}
\begin{algorithmic}
\For{$t = 1$ to $N$}
\Repeat
\State 1. Simulate $\theta'$ from $p(\theta)$
\State 2. Generate $x' \sim p(x|\theta')$
\Until{$\rho(\eta(x'), \eta(y)) \leq \epsilon$}
Accept $(\theta', x')$
\EndFor
\end{algorithmic}
\end{algorithm}

When $P_r(y|x, \theta) = I_{\mathcal{N}_r(y)}(x)$, as in our case, the acceptance probability $\alpha$ is decomposed into the product of the MCMC acceptance probability and the indicator function:

$$\alpha = \min \left\{ 1, \frac{p(\theta')q(\theta^{(n-1)}|\theta')}{p(\theta^{(n-1)})q(\theta'|\theta^{(n-1)})} \right\} I_{\mathcal{N}_r(y)}(x') \quad (6)$$

In this case, Step 3 is performed only if $x' \in \mathcal{N}_r(y)$. The efficiency of this algorithm is improved with respect to the Standard ABC algorithm, but Equation (6) clearly shows that the dependence upon $\epsilon$ in the indicator function may lead to an inefficient algorithm for a good approximation of the true posterior. In fact, given that $\alpha$ can only be non-zero if the event $\rho(\eta(x'), \eta(y)) \leq \epsilon$ occurs, the chain may persist in distributional tails for long periods of time if $\epsilon$ is sufficiently small, due to the acceptance probability being zero in Step 3 of Algorithm 2.

Some modifications to the ABC-MCMC scheme have been proposed that provide a moderate improvement in the simulation efficiency. See [13] for a complete tutorial about ABC-MCMC. More recently, to overcome this drawback associated with ABC-MCMC, a branch of computational techniques have emerged to obtain high accuracy ($\epsilon \to 0$) with a feasible computational burden by combining sequential sampling algorithms adapted for ABC. These techniques share a common principle of achieving computational efficiency by learning about intermediate target distributions determined by a decreasing sequence of tolerance levels $\epsilon_1 > \epsilon_2 > \ldots > \epsilon_m = \epsilon$, where the last is the desired tolerance $\epsilon$. Table 1 lists the main contributions to the literature on this topic. However, more research is needed to perform posterior simulations in a more efficient manner.

In this paper we introduce a new sequential algorithm, called Approximate Bayesian Computation based on Subset Simulation (ABC-SubSim), which combines the ABC principle with the technique of Subset
Simulation \cite{1,15,16} to achieve computational efficiency in a sequential way. The main idea is to link an ABC algorithm with a highly-efficient rare-event sampler that draws conditional samples from a nested sequence of subdomains defined in an adaptive and automatic manner. ABC-SubSim can utilize many of the improvements proposed in the recent ABC literature because of the fact that the algorithm is focused on the core simulation engine.

The paper is organized as follows. Section 2 reviews the theory underlying Subset Simulation and then the ABC-SubSim algorithm is introduced in Section 3. The efficiency of ABC-SubSim is illustrated in Section 4 with two examples of dynamical models with synthetic data. In Section 5, the performance of the algorithm is compared with some others in the recent ABC literature and the use of ABC-SubSim for posterior model class assessment is discussed. Section 6 provides concluding remarks.

2. Subset Simulation method

Subset Simulation is a simulation approach originally proposed to compute small failure probabilities encountered in reliability analysis of engineering systems (e.g. \cite{1,15,17}). Strictly speaking, it is a method for efficiently generating conditional samples that correspond to specified levels of a performance function \( g : \mathbb{R}^d \rightarrow \mathbb{R} \) in a progressive manner, converting a problem involving rare-event simulation into a sequence of problems involving more frequent events.

Let \( F \) be the failure region in the \( z \)-space, \( z \in Z \subset \mathbb{R}^d \), corresponding to exceedance of the performance function above some specified threshold level \( b \):

\[
F = \{ z \in Z : g(z) > b \} \quad (7)
\]

For simpler notation, we use \( P(F) \equiv P(z \in F) \). Let us now assume that \( F \) is defined as the intersection of \( m \) regions \( F = \bigcap_{j=1}^{m} F_j \), such that they are arranged as a nested sequence \( F_1 \supset F_2 \ldots \supset F_{m-1} \supset F_m = F \), where \( F_j = \{ z \in Z : g(z) > b_j \} \), with \( b_{j+1} > b_j \), such that \( p(z|F_j) \propto p(z) I_{F_j}(z) \), \( j = 1, \ldots, m \). The term \( p(z) \) denotes the probability model for \( z \). When the event \( F_j \) holds, then \( \{ F_{j-1}, \ldots, F_1 \} \) also hold, and hence \( P(F_j|F_{j-1}, \ldots, F_1) = P(F_j|F_{j-1}) \), so it follows that:

\[
P(F) = P\left( \bigcap_{j=1}^{m} F_j \right) = P(F_1) \prod_{j=2}^{m} P(F_j|F_{j-1}) \quad (8)
\]

where \( P(F_j|F_{j-1}) \equiv P(z \in F_j|z \in F_{j-1}) \), is the conditional failure probability at the \((j-1)\)th conditional level. Notice that although the probability \( P(F) \) can be relatively small, by choosing the intermediate regions appropriately, the conditional probabilities involved in Equation (8) can be made large, thus avoiding simulation of rare events.

In the last equation, apart from \( P(F_1) \), the remaining factors cannot be efficiently estimated by the standard Monte Carlo method (MC) because of the conditional sampling involved, especially at higher intermediate levels. Therefore, in Subset Simulation, only the first probability \( P(F_1) \) is estimated by MC:

\[
P(F_1) \approx \hat{P}_1 = \frac{1}{N} \sum_{n=1}^{N} \mathbb{1}_{F_1}(z_0^{(n)}) , \quad z_0^{(n)} \overset{i.i.d.}{\sim} p(z_0) \quad (9)
\]

When \( j \geq 2 \), sampling from the PDF \( p(z_{j-1}|F_{j-1}) \) can be achieved by using MCMC at the expense of generating \( N \) dependent samples, giving:

\[
P(F_j|F_{j-1}) \approx \hat{P}_j = \frac{1}{N} \sum_{n=1}^{N} \mathbb{1}_{F_j}(z_{j-1}^{(n)}) , \quad z_{j-1}^{(n)} \sim p(z_{j-1}|F_{j-1}) \quad (10)
\]

where \( \mathbb{1}_{F_j}(z_{j-1}^{(n)}) \) is the indicator function for the region \( F_j, j = 1, \ldots, m \), that assigns a value of 1 when \( g(z_{j-1}^{(n)}) > b_j \), and 0 otherwise.
Observe that the Markov chain samples that are generated at the \((j-1)\text{th}\) level which lie in \(F_j\) are distributed as \(p(z|F_j)\) and thus, they provide “seeds” for simulating more samples according to \(p(z|F_j)\) by using MCMC sampling with no burn-in required. As described further below, \(F_j\) is actually chosen adaptively based on the samples \(\{z_{j,n}^n|n = 1,\ldots,N\}\) from \(p(z|F_{j-1})\) in such a way that there are exactly \(NP_j\) of these seed samples in \(F_j\) (so \(\bar{P}_j = P_0\) in Equation 10). Then a further \((1/n_0 - 1)\) samples are generated from \(p(z|F_j)\) by MCMC starting at each seed, giving a total of \(N\) samples in \(F_j\). Repeating this process, we can compute the conditional probabilities of the higher-conditional levels until the final region \(F_m = F\) has been reached.

To draw samples from the target PDF \(p(z|F_j)\) using the Metropolis algorithm, a suitable proposal PDF must be chosen. In the original version of Subset Simulation \([1]\), a modified Metropolis algorithm (MMA) was proposed that works well even in very high dimensions (e.g. \(10^2\times 10^4\)), because the original algorithm fails in this case (essentially all candidate samples from the proposal PDF are rejected—see the analysis in \([1]\)). In MMA, a univariate proposal PDF is chosen for each component of the parameter vector and each component candidate is accepted or rejected separately, instead of drawing a full parameter vector candidate from a multi-dimensional PDF as in the original algorithm. Later in \([15]\), grouping of the parameters was considered when constructing a proposal PDF to allow for the case where small groups of components in the parameter vector are highly correlated when conditioned on any \(F_j\). An appropriate choice for the proposal PDF for ABC-SubSim is introduced in the next section.

It is important to remark that in Subset Simulation, an inadequate choice of the \(b_j\)-sequence may lead to the conditional probability \(P(F_j|F_j-1)\) being very small (if the difference \(b_j - b_{j-1}\) is too large), which will lead to a rare-event simulation problem. If, on the contrary, the intermediate threshold values were chosen too close so that the conditional failure probabilities were very high, the algorithm would take a large total number of simulation levels \(m\) (and hence large computational effort) to progress to the target region of interest, \(F\). A rational choice that strikes a balance between these two extremes is to choose the \(b_j\)-sequence adaptively \([1]\), so that the estimated conditional probabilities are equal to a fixed value \(P_0\) (e.g. \(P_0 = 0.2\)). For convenience, \(P_0\) is chosen so that \(NP_0 = 1/P_0\) are positive integers. For a specified value of \(P_0\), the intermediate threshold value \(b_j\) defining \(F_j\) is obtained in an automated manner as the \(\{(1-P_0)N\}^{th}\) largest value among the values \(g(z_{j,n}^\eta), n = 1,\ldots,N\), so that the sample estimate of 
\[P(F_j|F_j-1)\] in Equation 10 is equal to \(P_0\).

3. Subset Simulation for ABC

Here we exploit Subset Simulation as an efficient sampler for the inference of rare events by just specializing the Subset Simulation method described in \([12]\) to ABC. To this end, let us define \(z = (\theta, x) \in Z = \Theta \times D \subset \mathbb{R}^{d+\ell}\), so that \(p(z) = p(x|\theta)p(\theta)\). Let also \(F_j\) in \([12]\) be replaced by a nested sequence of regions \(D_j, j = 1,\ldots,m\) in \(Z\) defined by:
\[D_j = \{z \in Z : x \in N_{\epsilon_j}(y)\} = \{\theta, x : \rho(\eta(x), \eta(y)) \leq \epsilon_j\}\] (11)
with \(D_j \subset \Theta \times D\) and \(\rho\) is a metric on the set \(\{\eta(x) : x \in D\}\). The sequence of tolerances \(\epsilon_1, \epsilon_2, \ldots, \epsilon_m\), with \(\epsilon_{j+1} < \epsilon_j\), will be chosen adaptively as described in \([12]\) where the number of levels \(m\) is chosen so that \(\epsilon_m \leq \epsilon\), a specified tolerance.

As stated by Equation 11, an ABC algorithm aims at evaluating the sequence of intermediate posteriors \(p(\theta, x|D_j), j = 1,\ldots,m\), where by Bayes’ Theorem:
\[p(\theta, x|D_j) = \frac{P(D_j|\theta, x)p(x|\theta)p(\theta)}{P(D_j)} \propto I(D_j; (\theta, x))p(x|\theta)p(\theta)\] (12)
Here, \(I(D_j; (\theta, x))\) is the indicator function for the set \(D_j\). Notice that when \(\epsilon \to 0\), \(D_m\) represents a small closed region in \(Z\) and hence \(P(D_m)\) will be very small under the model \(p(\theta, x) = p(x|\theta)p(\theta)\). In this situation, using MCMC sampling directly is not efficient due to difficulties in initializing the chain and in achieving
convergence to the stationary distribution, as was described in §7 for ABC-MCMC. This is the point at which we exploit the efficiency of Subset Simulation for ABC, given that such a small probability $P(D_m)$ is converted into a sequence of larger conditional probabilities, as stated in Equations \[3, 9\] and \[10\].

3.1. The ABC-SubSim algorithm

Algorithm 3 provides a pseudocode implementation of ABC-SubSim that is intended to be sufficient for most situations. The algorithm is implemented such that a maximum allowable number of simulation levels \(m\) is considered in case the specified \(\epsilon\) is too small. The choice of \(\epsilon\) is discussed at the end of 3.1.2.

Algorithm 3 Pseudocode implementation for ABC-SubSim

Inputs:
- \(P_0 \in [0, 1]\) \{gives percentile selection, chosen so \(NP_0, 1/P_0 \in \mathbb{Z}^+\); \(P_0 = 0.2\) is recommended\}. 
- \(N\), \{number of samples per intermediate level\}; \(m\), \{maximum number of simulation levels allowed\}.

Algorithm:

Sample \(\left[\theta_0^{(1)}, x_0^{(1)}\right], \ldots, \left[\theta_0^{(n)}, x_0^{(n)}\right], \ldots, \left[\theta_0^{(N)}, x_0^{(N)}\right]\), where \(\{\theta, x\} \sim p(\theta)p(x|\theta)\)

for \(j = 1, \ldots, m\) do
  for \(n = 1, \ldots, N\) do
    Evaluate \(\rho_j^{(n)} = \rho(\eta(x^{(n)}_{j-1}), \eta(y))\)
  end for
  Remumber \(\left[\left(\theta_0^{(n)}, x_0^{(n)}\right), n : 1, \ldots, N\right]\) so that \(\rho_j^{(1)} \leq \rho_j^{(2)} \leq \ldots \rho_j^{(N)}\)
  Fix \(\epsilon_j = \frac{1}{\sigma} \left(\rho_j^{(NP_0)} + \rho_j^{(NP_0+1)}\right)\)
  for \(k = 1, \ldots, NP_0\) do
    Select as a seed \(\left(\theta_j^{(k)}{^{(1)}}, x_j^{(k)}{^{(1)}}\right) = \left(\theta_j^{(k)}{^{(1)}}, x_j^{(k)}{^{(1)}}\right) \sim p(\theta, x|\theta, x) \in D_j\)
    Run Modified Metropolis Algorithm [1] to generate \(1/P_0\) states of a Markov chain lying in \(D_j\)  (Eq. [11]): \(\left[\left(\theta_j^{(k)}{^{(1)}}, x_j^{(k)}{^{(1)}}\right), \ldots, \left(\theta_j^{(k)}{^{1/P_0}}, x_j^{(k)}{^{1/P_0}}\right)\right]\)
  end for
  Remumber \(\left(\theta_j^{(k)}{^{(1)}}, x_j^{(k)}{^{(1)}}\right): k = 1, \ldots, NP_0; i = 1, \ldots, 1/P_0\) as \(\left[\left(\theta_j^{(1)}, x_j^{(1)}\right), \ldots, \left(\theta_j^{(N)}, x_j^{(N)}\right)\right]\)
  if \(\epsilon_j \leq \epsilon\) then
    End algorithm
  end if
end for

3.1.1. Choice of intermediate tolerance levels

In Algorithm 3 the \(\epsilon_j\) values are chosen adaptively as in Subset Simulation [1], so that the sample estimate \(\hat{P}_j\) of \(P(D_j|D_{j-1})\) satisfies \(\hat{P}_j = P_0\). By this way, the intermediate tolerance value \(\epsilon_j\) can be simply obtained as the 100\(P_0\) percentile of the set of distances \(\rho(\eta(x^{(n)}_{j-1}), \eta(y))\), \(n = 1, \ldots, N\), arranged in increasing order. Additionally, for convenience of implementation, we choose \(P_0\) such that \(NP_0\) and \(1/P_0\) are integers, and so the size of the subset of samples generated in \(D_{j-1}\) that lie in \(D_j\) is known in advance and equal to \(NP_0\). These \(NP_0\) samples in \(D_j\) are used as seeds for \(NP_0\) Markov chains of length \(1/P_0\), where the new \((1/P_0 - 1)\) samples in \(D_j\) in each chain are generated by MMA [1]. Hence the total number of samples of \(\{\theta, x\}\) lying in \(D_j\) is \(N\), but \(NP_0\) of them were generated at the \((j - 1)\)th level. Because of the way the seeds are chosen, ABC-SubSim exhibits the benefits of perfect sampling [7, 18], which is an important feature to avoid wasting samples during a burn-in period, in contrast to ABC-MCMC.
3.1.2. Choosing ABC-SubSim control parameters

The important control parameters to be chosen in Algorithm 3 are \( p_0 \) and \( \sigma_j^2 \), the variance in the Gaussian proposal PDF in MMA at the \( j^{th} \) level. In this section we make recommendations for the choice of these control parameters.

In the literature, the optimal variance of a local proposal PDF for a MCMC sampler has been studied due to its significant impact on the speed of convergence of the algorithm [19, 20]. ABC-SubSim has the novelty of incorporating the Subset Simulation procedure in the ABC algorithm, so we use the same optimal adaptive scaling strategy as in Subset Simulation. To avoid duplication of literature for this technique but conferring a sufficient conceptual framework, the method for the optimal choice of the \( \sigma_j^2 \) is presented in a brief way. The reader is referred to the recent work of [18], where optimal scaling is addressed for Subset Simulation and a brief historical overview is also given for the topic.

Suppose that the reason for wanting to generate posterior samples is that we wish to calculate the posterior expectation of a quantity of interest which is a function \( h: \Theta \to \mathbb{R} \). We consider the estimate of its expectation with respect to the samples generated in each of the \( j^{th} \) levels:

\[
\hat{h}_j = \mathbb{E}_{p_\theta(D_j)}[h(\theta)] \approx \frac{1}{N} \sum_{n=1}^{N} h(\theta_j^{(n)})
\]

where \( \theta_j^{(n)}, n = 1, \ldots, N \) are dependent samples drawn from \( N_c \) Markov chains generated at the \( j^{th} \) conditional level. An expression for the variance of the estimator can be written as follows [1]:

\[
\text{Var}(\hat{h}_j) = \frac{B_j^{(0)}}{N}(1 + \gamma_j),
\]

with

\[
\gamma_j = 2 \sum_{\tau=1}^{N_s-1} \left( \frac{N_s - \tau}{N_s} \right) \frac{B_j^{(\tau)}}{B_j^{(0)}} \quad (15)
\]

In the last equation \( \gamma_j \) is the length of each of the Markov chains, which are considered probabilistically equivalent [1]. The term \( R_j^{(\tau)} \) is the autocovariance of \( h(\theta) \) at lag \( \tau \), \( R_j^{(\tau)} = \mathbb{E} [h(\theta^{(1)})h(\theta^{(1+\tau)})] - \bar{h}_j^2 \), which can be estimated using the Markov chain samples \( \{\theta_j^{(k,i)}: k = 1, \ldots, N_c; i = 1, \ldots, N_s\} \) as:

\[
R_j^{(\tau)} \approx \tilde{R}_j^{(\tau)} = \frac{1}{N - \tau N_s} \sum_{k=1}^{N_c} \sum_{i=1}^{N_s-\tau} h(\theta_j^{(k,i)})h(\theta_j^{(k,i+\tau)}) - \bar{h}_j^2
\]

where \( N_c = Np_0 \), so that \( N = N_c N_s \).

Given that the efficiency of the estimator \( \hat{h}_j \) is reduced when \( \gamma_j \) is high, the optimal proposal variance \( \sigma_j^2 \) for simulation level \( j^{th} \) is chosen adaptively by minimizing \( \gamma_j \). This configuration typically gives an acceptance rate \( \bar{\alpha} \) for each simulation level in the range of 0.2-0.4 [18]. This is supported by the numerical experiments performed with the examples in the next section, which leads to our recommendation for ABC-SubSim: *Adaptively choose the variance \( \sigma_j^2 \) of the \( j^{th} \) intermediate level so that the monitored acceptance rate \( \bar{\alpha} \in [0.2, 0.4] \) based on an initial chain sample of small length (e.g. 10 states).*

The choice of the conditional probability \( p_0 \) has a significant influence on the number of intermediate simulation levels required by the algorithm. The higher \( p_0 \) is, the higher the number of simulation levels employed by the algorithm to reach the specified tolerance \( \epsilon \), for a fixed number of model evaluations \( (N) \) per simulation level. This necessarily increases the computational cost of the algorithm. At the same time, the

\[\text{It is assumed for simplicity in the analysis that the samples generated by the different } N_c \text{ chains are uncorrelated under the performance function } h, \text{ although the samples are actually dependent because the seeds may be correlated. See further details in [1], Section 6.2.}\]
smaller $P_0$ is, the lower the quality of the posterior approximation, that is, the larger the values of $\gamma_j$ in Equation 14. The choice of $P_0$ therefore requires a trade-off between computational efficiency and efficacy, in the sense of quality of the ABC posterior approximation.

To examine this fact, let us take a fixed total number of samples, i.e. $N_T = mN$, where $m$ is the number of levels required to reach the target tolerance value $\epsilon$, a tolerance for which $R_m^{(0)} \approx \text{Var} [h(\theta)]$. The value of $m$ depends on the choice of $P_0$. We can choose $P_0$ in an optimal way by minimizing the variance of the estimator $\bar{h}_m$ for the last simulation level:

$$\text{Var}(\bar{h}_m) = \frac{R_m^{(0)}}{N_T/m} (1 + \gamma_m) \propto m (1 + \gamma_m)$$  (17)

Notice that $\gamma_m$ also depends upon $P_0$, although it is not explicitly denoted, as we will show later in §4 (Figure 2). In the original presentation of Subset Simulation in [1], $P_0 = 0.1$ was recommended, and more recently in [18], the range $0.1 \leq P_0 \leq 0.3$ was found to be near optimal after a rigorous sensitivity study of Subset Simulation, although the optimality there is related to the coefficient of variation of the failure probability estimate. The value $P_0 = 0.2$ for ABC-SubSim is also supported by the numerical experiments performed with the examples in the next section, where we minimize the variance in Equation 17 as a function of $P_0$, which leads to the recommendation: For ABC-SubSim, set the conditional probability $P_0 = 0.2$.

Finally, it is important to remark that an appropriate final tolerance $\epsilon$ may be difficult to specify a priori. For these cases, one recommendation is to select $\epsilon$ adaptively so that the posterior samples give a stable estimate $\bar{h}_m$ of $\mathbb{E}_{p_r(\theta|D_{	ext{sim}})} [h(\theta)]$ (Equation 13), i.e. a further reduction in $\epsilon$ does not change $\bar{h}_m$ significantly.

3.2. Evidence computation by means of ABC-SubSim

In a modeling framework, different model classes can be formulated and hypothesized to idealize the experimental system, and each of them can be used to solve the probabilistic inverse problem in Equation 11. If the modeler chooses a set of candidate model classes $M = \{M_k, k = 1, \ldots, N_M\}$, Bayesian model class assessment is a rigorous procedure to rank each candidate model class based on their probabilities conditional on data $y$ [21, 22].

$$P(M_k|y, M) = \frac{p(y|M_k)P(M_k|M)}{\sum_{i=1}^{N_M} p(y|M_i)P(M_i|M)}$$  (18)

where $P(M_k|M)$ is the prior probability of each $M_k$, that expresses the modeler’s judgement on the initial relative plausibility of $M_k$ within $M$. The factor $p(y|M_k)$, which is called the evidence (or marginal likelihood) for the model class, expresses how likely the data $y$ are according to the model class. The evidence $p(y|M_k)$ is equal to the normalizing constant in establishing the posterior PDF in Equation 11 for the model class $M_k$. $p(y|M_k) = \int_{\Theta} p(y|\theta, M_k)p(\theta|M_k)d\theta$.

When the likelihood is not available, the evidence $p(y|M_k)$ is approximated using ABC by $P_r(y|M_k)$, which depends upon $\epsilon$, the summary statistic $\eta(\cdot)$ as well as the chosen metric $\rho$ [23]. In terms of the notation in Equation 11, the ABC evidence can be expressed as:

$$P_r(y|M_k) = P(D_m|M_k) = \int_{\Theta} P(D_m|\theta, x, M_k)p(x|\theta, M_k)p(\theta|M_k)d\theta dx$$  (19)

The evaluation of the last integral is the computationally expensive step in Bayesian model selection, especially when $\epsilon \rightarrow 0$ [3]. Observe that $P_r(y|M_k)$ in Equation 19 is expressed as a mathematical expectation that can be readily estimated as follows:

$$P_r(y|M_k) \approx \frac{1}{N} \sum_{n=1}^{N} I_{D_m}(\theta^{(n)}, x^{(n)})$$  (20)

3The model parameter vector $\theta$ will, in general, be different for different model classes $M_k$. 8
where \((\theta^{(n)}, x^{(n)}) \sim p(x|\theta, M_k)p(\theta|M_k)\) are samples that can be drawn using the Standard ABC algorithm (Algorithm 1), which in this setting is equivalent to the Standard Monte Carlo method for evaluating integrals. The main drawback of this method arises when employing \(\epsilon \to 0\), due to the well-known inefficiency of the Standard ABC algorithm. Moreover, the quality of the approximation in Equation (24) may be poor in this situation unless a huge amount of samples are employed because otherwise the Monte Carlo estimator has a large variance. Hence, several methods have emerged in the ABC literature to alleviate this difficulty, with the main drawback typically being the computational burden. See [24] for discussion of this topic.

ABC-SubSim algorithm provides a straight-forward way to approximate the ABC evidence \(P_r(y|M_k)\) via the conditional probabilities involved in Subset Simulation:

\[
P_r(y|M_k) = P(D_0|M_k) = P(D_1) \prod_{j=2}^{m} P(D_j|D_{j-1}) \approx P_0^m
\]  

(21)

The last is an estimator for \(P_r(y|M_k)\) which is asymptotically unbiased with bias \(O(1/N)\). See [1, 18] for a detailed study of the quality of the estimators based on Subset Simulation where the approximation is studied in the context of the failure probability estimate (but notice that Equations 21 and 8 are essentially the same). Of course, there are also approximation errors due to the ABC approximation that depend on the choice of \(\epsilon, \eta(\cdot)\) and \(\rho\) [23]. Finally, once \(P_r(y|M_k)\) is calculated, it is substituted for \(p(y|M_k)\) in Equation (18) to obtain \(P_r(M_k|y, M)\), the ABC estimate of the model class posterior probability. It is important to remark here that there are well-known limitations of the ABC approach to the model selection problem, typically attributable to the absence of sensible summary statistics that work across model classes, among others [23, 24]. Our objective here is to demonstrate that calculation of the ABC evidence is a simple by-product of ABC-SubSim, as given in Equation (21).

4. Illustrative examples

In this section we illustrate the use of ABC-SubSim with two examples: 1) a moving average process of order \(d = 2\), MA(2), previously considered in [3]; 2) a single degree-of-freedom (SDOF) linear oscillator subject to white noise excitation, which is an application to a state-space model. Both examples are input-output type problems, in which we adopt the notation \(y = [y_1, \ldots, y_t, \ldots, y_T]\) for the measured system output sequence of length \(T\). The objective of these examples is to illustrate the ability of our algorithm to be able to sample from the ABC posterior for small values of \(\epsilon\). In the MA(2) example, we take for the metric the quadratic distance between the \(d = 2\) first autocovariances, as in [3]:

\[
\rho(\eta(x), \eta(y)) = \sum_{q=1}^{d} (\tau_{y,q} - \tau_{x,q})^2
\]  

(22)

In the last equation, the terms \(\tau_{y,q}\) and \(\tau_{x,q}\) are the autocovariances of \(y\) and \(x\), respectively, which are used as summary statistics. They are obtained as \(\tau_{y,q} = \sum_{k=q+1}^{t} y_k y_{k-q}\) and \(\tau_{x,q} = \sum_{k=q+1}^{t} x_k x_{k-q}\), respectively. The Euclidean distance of \(x\) from \(y\) is considered as the metric for the oscillator example:

\[
\rho(x, y) = \left[ \sum_{i=1}^{T} (y_i - x_i)^2 \right]^{1/2}
\]  

(23)

To evaluate the quality of the posterior, we study the variance of the mean estimator of a quantity of interest \(h: \theta \in \Theta \to \mathbb{R}\), defined as follows (see [3, 12]):

\[
h(\theta) = \sum_{i=1}^{d} (\theta_i)^2 = \|\theta\|^2_2
\]  

(24)
4.1. Example 1: Moving Average (MA) model

Consider a MA(2) stochastic process, with \( x_l, l = 1, \ldots, \ell \), the stochastic variable defined by:

\[
x_l = e_l + \sum_{i=1}^{d} \theta_i e_{l-i}
\]

with \( d = 2, \ell = 100 \) or 1000. Here \( e \) is an i.i.d sequence of standard Gaussian distributions \( \mathcal{N}(0,1) \): \( e = [e_{-d+1}, \ldots, e_0, e_1 \ldots e_{l-1}, e_l] \) and \( x = [x_1, \ldots, x_l, \ldots, x_l] \). To avoid unnecessary difficulties, a standard identifiability condition is imposed on this model \[3\], namely that the roots of the polynomial \( \Delta(\xi) = 1 - \sum_{i=1}^{d} \theta_i \xi^i \) are outside the unit circle in the complex plane. In our case of \( d = 2 \), this condition is fulfilled when the region \( \Theta \) is defined as all \((\theta_1, \theta_2)\) that satisfy:

\[-2 < \theta_1 < 2; \theta_1 + \theta_2 > -1; \theta_1 - \theta_2 < 1\]

The prior is taken as a uniform distribution over \( \Theta \).

Note that, in principle, this example does not need ABC methods as the likelihood is a multidimensional Gaussian with zero mean and a covariance matrix of order \( \ell \) that depends on \((\theta_1, \theta_2)\), but its evaluation requires a considerable computational effort when \( \ell \) is large \[25\]. This example was also used to illustrate the ABC method in \[3\] where it was found that the performance is rather poor if the metric is the one in Equation \[25\] which uses the “raw” data but ABC gave satisfactory performance when the metric in Equation \[22\] was used. For comparison with Figure 1 \[3\], we also choose the latter here.

We use synthetic data for \( y \) by generating it from Equation \[25\] considering \( \theta_{true} = (0.6, 0.2) \). The chosen values of the control parameters for ABC-SubSim are shown in Table \[2\]. The ABC-SubSim results are presented in Figure \[4\] which shows that the mean estimate of the “approximate” posterior samples at each level is close to \( \theta_{true} \), for both \( \ell = 100 \) and \( \ell = 1000 \) cases. Figure \[1\] shows the case \( \ell = 100 \) which can be compared with Figure 1 in \[3\]. In Figure \[1\] a total of 3000 samples were used to generate 1000 samples to represent the posterior, whereas in \[3\], 1,000,000 samples were used to generate 1000 approximate posterior samples using the standard ABC algorithm that we called Algorithm \[1\]. The ABC-SubSim posterior samples give a more compact set that is better aligned with the exact posterior contours given in Figure 1 of \[3\]. Figure \[1\] shows that for the case \( \ell = 1000 \), ABC-SubSim used 4000 samples to generate 1000 samples representing the much more compact posterior that corresponds to ten times more data.

A preliminarily sensitivity study was done to corroborate the choice of the algorithm control parameters described in \[3.1.2\] and the results are shown in Figure \[2\]. As described in \[3.1.2\], the optimal value of \( P_0 \) is the one that minimizes \( m(1 + \gamma_m) \) for fixed tolerance \( \epsilon \). As an exercise, we consider \( \epsilon = 1.12 \cdot 10^4 \) as the final tolerance. The results in Figure \[2\] show that \( P_0 = 0.2 \) is optimal since then \( m(1 + \gamma_m) = 3(1 + 2.8) = 11.4 \); whereas for \( P_0 = 0.5 \) and \( P_0 = 0.1 \), it is \( 7(1 + 0.86) = 13.1 \) and \( 2(1 + 5.1) = 12.2 \), respectively. These results are consistent with those for rare event simulation in \[18\]. Observe also that the optimal variance \( \sigma_j^2 \) for the Gaussian proposal PDF at the \( j^{th} \) level that minimizes \( \gamma_j \) occurs when the acceptance rate \( \alpha_j \) in MMA lies in the range 0.2-0.4, which is also consistent with that found in \[18\] (except for the case of very low acceptance rate where the process is mostly controlled by the noise).

4.2. Example 2: Linear oscillator

Consider the case of a SDOF oscillator subject to white noise excitation as follows:

\[
m\ddot{x} + c\dot{x} + kx = f(t)
\]

where \( x = \xi(t) \in \mathbb{R} [m] \), \( m \ [Kg] \), \( k \ [N/m] \) and \( c \ [N \cdot s/m] \) are the displacement, mass, stiffness and damping coefficient, respectively. To construct synthetic input, a discrete-time history of input force \( f[N] \) modeled by Gaussian white noise with spectral intensity \( S_f = 0.0048 [N^2 \cdot s] \), is used. The time step used to generate

\[4\]

It is unlikely that one or more values from the \( \epsilon \)-sequence obtained using different \( P_0 \) values coincide exactly. Hence, the nearest value to the final tolerance is considered for this exercise.
the input data is 0.01 [s], which gives an actual value for the variance of the discrete input force $\sigma_f^2 = 3 [N]$. The probability model that gives the likelihood function of this example is Gaussian and so it can be written explicitly although its evaluation requires the computation of a high dimensional matrix inverse. Repeated evaluations of the likelihood function for thousands of times in a simulation-based inference process is computationally prohibitive for large-size datasets. However it is easy to simulate datasets from this model after some trivial manipulations of Equation 26. Therefore, this example is particularly suited for the use of ABC methods.

The mechanical system is assumed to have known mass $m = 3 [Kg]$ and known input force giving the excitation. For the state-space simulation, denote the state vector by $s(t) = [\xi(t), \dot{\xi}(t)]^T$. Equation 26 can be rewritten in state-space form as follows:

$$\dot{s}(t) = A_c s(t) + B_c f(t)$$

where $A_c \in \mathbb{R}^{2 \times 2}$, $B_c \in \mathbb{R}^{2 \times 1}$ are obtained as:

$$A_c = \begin{pmatrix} 0 & 1 \\ -m^{-1}k & -m^{-1}c \end{pmatrix}, \quad B_c = \begin{pmatrix} 0 \\ m^{-1} \end{pmatrix}$$

By approximating the excitation as constant within any interval, i.e. $f(l\Delta t + \tau) = f(l\Delta t), \forall \tau \in [0, \Delta t)$, Equation 27 can be discretized to a difference equation:

$$s_l = As_{l-1} + B_f f_{l-1}$$

with $s_l = \{s(l\Delta t), f_l, l = 0, 1, 2, \ldots, \ell\}$ and $A$ and $B$ are matrices given by:

$$A = e^{A_c \Delta t}$$
$$B = A_c^{-1} (A - I_2) B_c$$

where $I_2$ is the identity matrix of order 2. The use of discrete-time input and output data here is typical of the electronically-collected data available from modern instrumentation on mechanical or structural systems.

We adopt $\theta = \{k, c\}$ as unknown model parameters and denote by $y_l$ and $x_l$ the vectors consisting of the actual and predicted response measurements at each $\Delta t$. Samples of $x_l$ for a given input force time history $\{f_l\}$ and $\theta$, can be readily generated by the underlying state-space model:

$$s_l = As_{l-1} + B f_{l-1} + e_l$$
$$x_l = [1, 0] s_l + e_l'$$

where $e_l$ and $e_l'$ are error terms to account for model prediction error and measurement noise, respectively. Since in reality these errors would be unknown, we use the Principle of Maximum Information Entropy 2, 29, 30 to choose $e_l$ and $e_l'$ as i.i.d. Gaussian variables, $e_l \sim N(0, \sigma_e^2 I_2)$, $e_l' \sim N(0, \sigma_{e'}^2)$ and so they can be readily sampled. For simplicity, we adopt $\sigma_e^2 = 10^{-2}$ and $\sigma_{e'}^2 = 10^{-6}$, taking them as known. We call $y = \{y_1, y_2, \ldots, y_T\}$ the batch dataset collected during a total period of time $l = \ell \Delta t$, starting from known initial conditions $s_0 = [0.01, 0.03]^T$ (units expressed in $[m]$ and $[m/s]$ respectively). In this example, the noisy measurements $y_l$ are synthetically generated from Equation 31 for the given input force history and for model parameters $\theta_{true} = \{k = 4\pi, c = 0.4\pi\}$. We also adopt a sampling rate for the resulting output signal of 100 [Hz] ($\Delta t = 0.01 [s]$) during a sampling period of $t = 3 [s]$, hence $\ell = 300$. We choose a uniform prior over the parameter space $\Theta$ defined by the region $0 < \theta_i \leq 3; i \in \{1, 2\}$. Table 2 provides the information for the algorithm configuration.

The results shown in Figure 3 are very satisfactory in the sense that ABC-SubSim can reconstruct the true signal with high precision with only a moderate computational cost. The posterior samples show that in Bayesian updating using noisy input-output data, the stiffness parameter $k = 4\pi \theta_1$ is identified with much less uncertainty that the damping parameter $c = 0.4\pi \theta_2$. The normalized mean value over the set of posterior samples corresponding to the smallest value of $\epsilon$ is $\hat{\theta} = (1.00, 0.03)$, which is very close to the normalized true value $\theta_{true} = (1.0, 1.0)$, (even if the exact likelihood was used, we would not expect $\hat{\theta} = \theta_{true}$ because of the noise in the synthetic data $y$).
5. Discussion

5.1. Comparison with recent sequential ABC algorithms

In this section, ABC-SubSim is compared with a selection of recent versions of sequential ABC algorithms: ABC-SMC [31], ABC-PMC [32] and ABC-PT [33], which are listed in Table 1. The same number of evaluations per simulation level are adopted for all algorithms, corresponding to 1000 and 2000 for the MA(2) and SDOF model, respectively. We set the sequence of tolerance levels obtained by ABC-SubSim using $P_0 = 0.5$ for the rest of the algorithms (see Table 3). This was done because the recommended near-optimal value of $P_0 = 0.2$ (see §3.1.2) for ABC-SubSim produced a sequence of $\epsilon$ values that decreased too quickly for ABC-PMC and ABC-SMC to work properly. We note that this non-optimal choice of $P_0$ for ABC-SubSim and the use of its $\epsilon$-sequence provide considerable help for the competing algorithms. The proposal PDFs are assumed to be Gaussian for all of the algorithms.

The results shown in Figure 4 are evaluated over the intermediate posterior samples for each simulation level and were obtained considering the mean of 100 independent runs of the algorithms, a large enough number of runs to ensure the convergence of the mean. In this example, we focus on the number of model evaluations together with the quality of the posterior. The left side of Figure 4 shows the accumulated amount of model evaluations employed by each of the competing algorithms. Note that each algorithm requires the evaluation of auxiliary calculations, like those for the evaluation of particle weights, transition kernel steps, etc. However, this cost is negligible because the vast proportion of computational time in ABC is spent on simulating the model repeatedly. The number of model evaluations for ABC-PMC and ABC-PT is variable for each algorithm run, so in both cases we present the mean (labelled dotted lines) and a 95% band (dashed lines). In contrast, ABC-SubSim and also ABC-SMC make a fixed number of model evaluations at each simulation level. Observe that the computational saving is markedly high when comparing with ABC-PMC.

Regarding the quality of the posterior, we consider two measures: a) the sample mean of the quadratic error between $\hat{\theta}$ and $\theta_{true}$, i.e., $\|\hat{\theta}_j - \theta_{true}\|^2_2$, as an accuracy measure; and b) the differential entropy of the final posterior, by calculating $1/2 \ln [(2\pi e)^d \det [\text{cov}(\theta_j)]]$, as a measure quantifying the posterior uncertainty of the model parameters. The results are shown on the right side of Figure 4. Only the last 4 simulation levels are presented for simplicity and clarity.

This comparison shows that ABC-SubSim gives the same, or better, quality than the rest of the ABC algorithms to draw ABC posterior samples when $\epsilon$ is small enough, even though it used a smaller number of model evaluations.

5.2. Evidence calculation

In this section we show how ABC-SubSim algorithm can be applied to estimate the ABC evidence by taking advantage of the improvements in parameter space exploration introduced by Subset Simulation. Table 4 shows the estimated values of the ABC evidence obtained with the ABC-SubSim algorithm ($P_0 = 0.2$), which are computed using a total number of samples per simulation level $N$ equal to 1000 and 2000 for MA(2) and SDOF model, respectively. For each value of $\epsilon_j$ chosen adaptively by ABC-SubSim as described in §3.1.2, we also calculate the ABC evidence using the approximation in Equation 20 with $N = 200,000$ samples per $\epsilon$ value for the Standard ABC algorithm (a large enough amount of samples for the approximation in Equation 20 to be sufficiently accurate). It is seen in both examples that the results obtained by ABC-SubSim and Standard ABC agree well.

These results suggest that if the well-known difficulties of the ABC model choice problem can be adequately resolved, high efficiency can be obtained by employing the ABC-SubSim algorithm for the ABC evidence computation.

---

5. This expression for the differential entropy is actually an upper-bound approximation to the actual differential entropy, where the exactness is achieved when the posterior PDF is Gaussian.
6. Conclusions

A new ABC algorithm based on Markov Chain Monte Carlo has been presented and discussed in this paper. This algorithm combines the principles of Approximate Bayesian Computation (ABC) with a highly-efficient rare-event sampler, Subset Simulation, which draws conditional samples from a nested sequence of subdomains defined in an adaptive and automatic manner. We demonstrate the computational efficiency that can be gained with ABC-SubSim by two different examples that illustrate some of the challenges in real-world applications of ABC. The main conclusions of this work are:

- By its construction, ABC-SubSim avoids the difficulties of ABC-MCMC algorithm in initializing the chain, as no burn-in is required.
- In comparison with other recent sequential ABC algorithms, ABC-SubSim requires a smaller number of model evaluations per simulation level to maintain the same quality of the posterior as the other algorithms.
- Together with ABC-SMC from [31], ABC-SubSim does not require the specification of a sequence of tolerance levels, which avoids tedious preliminary calibrations.
- ABC-SubSim allows a straightforward way to obtain an estimate of the ABC evidence used for model class assessment.

| MA(2) ($\times 10^4$) | 122 | 50.2 | 21.7 | 9.61 | 4.57 | 2.29 | 1.12 | 0.56 | 0.28 | 0.14 |
| Oscillator | 0.0117 | 0.0099 | 0.0082 | 0.0054 | 0.0040 | 0.0030 | 0.0024 | 0.0020 | 0.0018 | 0.0016 |
Table 4: Results of the estimation of the ABC evidence $P_{\epsilon_j}(D_j|M)$ for the MA(2) and oscillator examples when using 4 different tolerance values $\epsilon_j, j = 1, \ldots, 4$, which are produced by the ABC-SubSim algorithm with $P_0 = 0.2$. The Standard ABC algorithm employing 200,000 samples is also used to estimate $P_{\epsilon_j}(D_j|M)$ as in Equation 20.

| Example 1: MA(2) | SubSim | Standard ABC |
|------------------|--------|--------------|
| $(\epsilon_1 = 3.77 \cdot 10^5)$ | 0.2 | 0.2070 |
| $(\epsilon_2 = 5.58 \cdot 10^4)$ | 0.04 | 0.0412 |
| $(\epsilon_3 = 1.16 \cdot 10^4)$ | 0.008 | 0.0078 |
| $(\epsilon_4 = 2.25 \cdot 10^3)$ | 0.0016 | 0.0017 |

| Example 2: Oscillator | SubSim | Standard ABC |
|-----------------------|--------|--------------|
| $(\epsilon_1 = 0.0053)$ | 0.2 | 0.2038 |
| $(\epsilon_2 = 0.0023)$ | 0.04 | 0.0397 |
| $(\epsilon_3 = 0.0016)$ | 0.008 | 0.0079 |
| $(\epsilon_4 = 0.0014)$ | 0.0016 | 0.0016 |
