Purpose: Low socioeconomic status is associated with higher prevalence of diabetes, worse outcomes, and worse quality of care. We explored the relationship between education, as a measure of socioeconomic status, and quality of care in the Swiss context.

Patients and methods: Data were drawn from a population-based survey of 519 adults with diabetes during fall 2011 and summer 2012 in a canton of Switzerland. We assessed patients and diabetes characteristics. Eleven indicators of quality of care were considered (six of process and five of outcomes of care). After bivariate analyses, regression analyses adjusted for age, sex, and diabetic complications were performed to assess the relationship between education and quality of care.

Results: Of 11 quality-of-care indicators, three were significantly associated with education: funduscopy (patients with tertiary versus primary education were more likely to get the exam: odds ratio, 1.8; 95% confidence interval [CI], 1.004–3.3) and two indicators of health-related quality of life (patients with tertiary versus primary education reported better health-related quality of life: Audit of Diabetes-Dependent Quality of Life: β=0.6 [95% CI, 0.2–0.97]; SF-12 mean physical component summary score: β=3.6 [95% CI, 0.9–6.4]).

Conclusion: Our results suggest the presence of educational inequalities in quality of diabetes care. These findings may help health professionals focus on individuals with increased needs to decrease health inequalities.

Keywords: primary care, education, quality of care, diabetes

Introduction
Diabetes and many other chronic diseases show a higher prevalence among groups of low socioeconomic status (SES). In addition, patients with diabetes and a low SES have been shown to present with worse health outcomes such as poorer glycemic control, more diabetes-related complications, higher cardiovascular risk factors, and poorer self-rated health.

A model has been proposed by Brown et al to explain this association between SES and health outcomes in patients with diabetes. It suggests that health outcomes (which show the effects of care on the health status of patients) are influenced by distal factors, such as individual (eg, cultural background) or community characteristics, as well as by more proximal factors such as health behaviors, access to health care, and processes of care (ie, what is done to care for a patient). Most studies looking at the relationship between SES and processes of diabetes care reported worse processes of care among patients of lower SES. It is well accepted that processes of care influence diabetes outcomes, and many processes are considered indicators of quality...
of diabetes care. Thus, achieving optimal processes of care is postulated to be a key element in the care of patients with diabetes.

In Switzerland, health insurance is mandatory, and access to care is universal. Despite that, health inequalities across SES groups have been reported, mostly for mortality and cardiovascular risk factors. Moreover, recent studies have shown that individuals with low income were at high risk of foregoing healthcare for economic reasons, possibly because of the high out-of-pocket payments characterizing the Swiss health care system. However, it remains unknown whether once individuals have reached the health care system, social inequalities persist with regard to quality of care. Indeed, no study in Switzerland has so far examined the relationship between education and quality of care in any disease.

The aim of this study was to determine the association between education and quality of care among patients with diabetes.

**Material and methods**

**Setting and patients**

We used data from a cross-sectional paper survey, self-administered among a cohort of patients with any type of diabetes, living in the canton of Vaud, a large French-speaking region in Switzerland with more than 720,000 inhabitants. Adults (aged ≥18 years) presenting with a prescription for insulin, oral antidiabetics, glycemic strips, or a glucose meter were recruited by pharmacists in fall 2011 and summer 2012. Fifty-six of the 140 randomly contacted pharmacies agreed to participate. Although pharmacists checked the eligibility of the patients and presented the study, patients willing to participate were asked to fill in the questionnaire at home and send it back to the investigators. Patients with an obvious cognitive impairment, those who did not speak or understand French well enough, those who did not reside in the canton of Vaud, and women with gestational diabetes were excluded. With patients’ approvals, treating physicians were contacted and asked to fill in a brief questionnaire to collect some laboratory and clinical data. The final sample totaled 519 patients (406 from 1,013 eligible patients in 2011 and 63% in 2012). Physicians’ reported values were the most outcomes of care considered were reported by the treating physicians (162 physicians reported the values of HbA1c level check (yes, one time; yes, more than one time; no; or I do not know), lipid blood test (yes, no, or I do not know), microalbuminuria test (yes, no, or I do not know), funduscopy (yes, less than 1 year ago; yes, 1–2 years ago; yes, more than 2 years ago; never; or I do not know), feet examined by a physician (yes, no, or I do not know), and influenza vaccination (yes, no, or I do not know). We also regrouped “do not know” answers into the missing answer category. For the HbA1c variable, we only considered the answers of patients reporting knowing the meaning of HbA1c (skip question).

**Measures**

The variables considered in this study included one exposure variable, several dependent variables, and other independent variables considered as potential confounders.

**Education**

The exposure variable was self-reported education, which is one of several dimensions of socioeconomic status. It was grouped into three categories according to the International Standard Classification of Education: primary education, corresponding to the completion of compulsory school or less; secondary education, corresponding to vocational training or high school; and tertiary education, corresponding to university or technical college.

**Processes of care (dependent variables)**

Patients were asked whether they had received the following processes of care during the last 12 months: HbA1c level check (yes, one time; yes, more than one time; no; or I do not know), lipid blood test (yes, no, or I do not know), microalbuminuria test (yes, no, or I do not know), funduscopy (yes, less than 1 year ago; yes, 1–2 years ago; yes, more than 2 years ago; never; or I do not know), feet examined by a physician (yes, no, or I do not know), and influenza vaccination (yes, no, or I do not know). We also regrouped “do not know” answers into the missing answer category. For the HbA1c variable, we only considered the answers of patients reporting knowing the meaning of HbA1c (skip question).

**Outcomes of care (dependent variables)**

Most outcomes of care considered were reported by the treating physicians (162 physicians reported the values of 271 patients, for a physicians’ participation rate of 60% in 2011 and 63% in 2012). Physicians’ reported values were the following: last measured value of HbA1c (%), systolic blood pressure (mmHg), and low-density lipoprotein cholesterol (mmol/L). We also considered patient-reported health-related quality of life (HRQoL), as measured by two indicators: a disease-specific measure, the Audit of Diabetes-Dependent Quality of Life, with values ranging between −9 (maximum negative effect of diabetes) and +3 (maximum positive effect of diabetes), and a generic instrument, the SF-12. The results of the SF-12 are expressed with two scores: the mental component summary and physical component summary scores, with each having been initially constructed so as to present a mean of 50 and a standard deviation of 50.
### Table 1 Descriptive analyses

| Characteristics of participants | N   |  
|-------------------------------|-----|
| Women                         | 519 | 40.3% |
| Mean age, years (standard deviation) | 519 | 64.5 (11.3) |
| Diabetes type 2               | 480 | 72.3% |
| Mean household income per month, Swiss francs<br>&lt;3,499 | 21.2%  
| 3,500–5,499                  | 26.3%  
| 5,500–9,499                  | 27.8%  
| &gt;9,500                    | 17.3%  |
| Education                     | 504 |  
| Primary                       | 18.9%  |
| Secondary                     | 56.2%  |
| Tertiary                      | 25.0%  |
| Participated in a diabetes management course | 507 |  
| Yes, &gt;2 years ago          | 22.3%  |
| Yes, =2 years ago             | 10.5%  |
| Visited the GP at least once during the last 12 months | 473 | 93.7%  |
| At least one diabetes complication | 505 | 47.5%  |
| Processes of care             |  
| Received HbA1c check last year* | 280 | 98.9%  |
| Received lipid check last year | 500 | 96.6%  |
| Received microalbuminuria check last year | 436 | 74.3%  |
| Received funduscopy last year | 503 | 59.1%  |
| Received feet examination last year | 506 | 67.0%  |
| Received influenza vaccination last year | 513 | 63.9%  |
| Outcomes of care              |  
| Mean last HbA1c value, % (standard deviation) | 268 | 7.2 (1.2) |
| Mean systolic blood pressure value, mmHg (standard deviation) | 270 | 133.6 (15.7) |
| Mean LDL value, mmol/L (standard deviation) | 242 | 2.6 (0.9) |
| SF-12 score (standard deviation) | 498 | 43.4 (10.5) |
| Mean mental component summary score (standard deviation) | 496 | 47.0 (11.2) |
| Audit of Diabetes-Dependent Quality of Life, mean score (standard deviation) | 512 | –1.6 (1.6) |

### Results

The study participants had a mean age of 64.5 years, 40.3% were women, and 47.5% had at least one diabetes complication. Educational status distribution was as follows: 18.9% primary, 56.2% secondary, and 25.0% tertiary education (Table 1). In bivariate analyses (Tables 2 and 3), the proportion of patients having received feet examination grew from primary to tertiary education, with a statistically significant trend. Bivariate analyses of outcomes of care showed that diabetes-specific and generic quality-of-life measures significantly increased with increasing educational level.

Fully adjusted regressions showed a general pattern of higher quality of care among patients with higher educational levels (Table 4). Funduscopy was the only process of care significantly associated with education: patients with tertiary education were more likely to receive a funduscopy.

### Other independent variables

Further covariates considered were age, sex, and the presence (yes/no) of diabetes-related complications (cardiovascular disease, stroke, vision problems not including cataracts or glaucoma, chronic kidney insufficiency, dialysis or kidney transplantation, foot neuropathy, foot ulcer, amputation of a lower limb, and severe hypo- or hyperglycemia).

### Statistical analyses

Bivariate analyses were first carried out between education and dependent variables (processes and outcomes of care), using chi square test and analysis of variance for categorical and continuous variables, respectively. We further built linear and logistic regression models to assess the association between education and processes and outcomes of care, respectively. We adjusted all final models for age, sex, and the presence of diabetes-related complications, variables considered to be potential confounders of the association of interest. To take into account the intragroup correlation (clusters of pharmacies), the clustered sandwich estimator was used to estimate the variance-covariance matrix. Analyses were performed using Stata 12.1. P values &lt;0.05 were considered statistically significant.

### Table 2 Proportion of participants who received diabetes-related checks by level of education

| Processes of care | HbA1c check* | Lipid check | Microalbuminuria check | Funduscopy | Feet examination* | Influenza vaccination |
|-------------------|--------------|-------------|------------------------|------------|------------------|----------------------|
| Education         | n=326        | n=486      | n=422                  | n=489      | n=492            | n=498                |
| Primary, %        | 96.3         | 96.6       | 75.3                   | 51.1       | 59.3             | 59.1                 |
| Secondary, %      | 98.9         | 97.5       | 74.3                   | 61.9       | 65.9             | 64.8                 |
| Tertiary, %       | 98.8         | 96.8       | 73.1                   | 60.3       | 73.6             | 66.1                 |

**Notes:** *Among patients who know what HbA1c means; ‡P value for trend &lt;0.05.

**Abbreviation:** HbA1c, glycosylated hemoglobin.
than those with primary education (odds ratio, 1.8; 95% confidence interval, 1.004–3.3). Analyses of outcome variables showed that only HRQoL was significantly associated with education. In fact, patients with secondary and tertiary education had a higher quality of life, as measured by the Audit of Diabetes-Dependent Quality of Life and the physical component summary score of the SF-12 compared with patients with primary education.

**Discussion**

This study suggests the presence of social inequalities in the care of patients with diabetes, even in a wealthy country with universal health insurance coverage. More specifically, we found educational disparities for one process of care (funduscropy) and HRQoL.

**Processes of care**

Our results are consistent with most studies assessing the relationship between SES and processes of diabetes care, which report, with few exceptions, an association between lower SES and worse processes of care. Indeed, low SES has been associated with worse diabetes education and poorer use of annual medical checks. A direct comparison to these findings is, however, rather difficult, as almost every study selected different sets of processes and outcomes of care. Our results nevertheless remain consistent with the literature, insofar as funduscropy is the process of care that has been most often related to lower SES. This may be explained by the fact that this exam has to be performed by a specialist, unlike the other considered processes of care. In fact, a better-educated patient may be more likely to get an appointment directly with a specialist or to remind his general practitioner to refer him. Further, such a patient may also better understand what was done and better self-report the exam. Finally, our other processes of care share a feature that may explain their lack of association with education: they are all routinely performed and can all be performed in a general practitioner’s practice.

**Outcomes of care**

In line with other research, we also found that patients with lower education reported lower diabetes-specific and generic

**Table 3** Mean values of outcomes of care by level of education

| Outcomes of care | Last HbA1c value, % [mmol/mol] | Systolic blood pressure, mmHg | LDLc, mmol/L | SF-12, mean physical component summary score | SF-12, mean mental component summary score | Audit of diabetes-dependent quality of life: mean score |
|------------------|---------------------------------|-------------------------------|--------------|-----------------------------------------------|---------------------------------------------|-------------------------------------------------|
| Education        | 7.1 [54]                        | 132.8                         | 2.6          | 41.0 [47.0]                                  | 45.0 [2.6]                                  | 0.8 (0.5–1.5)                                  |

Our hypothesis is that a better education may contribute to increased HRQoL through better understanding of the nature of the disease, better coping with the disease, and eventually better diabetes care overall. Most of these associations were, however, not clinically significant.

The population-based design and the use of many processes and outcomes of care are the main strengths of this study. Yet our findings have limitations, with one issue being the selection bias resulting from a moderate participation rate and recruitment of patients in pharmacies. However, this is more likely to have introduced an underestimation than an overestimation of the association between education and quality of life by excluding individuals of the lowest socioeconomic groups. Indeed, individuals not proficient in French were excluded at enrollment, and a prerequisite to study participation was a visit to the pharmacy. These individuals (of low SES) are also more difficult to recruit for studies. In our study, people of lower SES may have visited a pharmacy less often than more wealthy individuals, and thus may have been less likely to be recruited. However, we are confident that our population sample is representative, as some characteristics of our study patients were similar to those of a prior study conducted in the same region. Another limitation was the sample size, which was not planned for the objective of the present analysis. As a possible consequence, we may not have had enough power to always detect statistically significant differences, despite suggestive and consistent trends toward SES inequalities in quality of care. Finally, self-reported data are prone to recall bias, which may have affected our process and outcome measures.

**Conclusion**

Achieving good quality of care is essential for individuals with diabetes, as it can decrease their mortality and morbidity risks. Recent studies have shown that tailored interventions for socially disadvantaged patients can have positive effects on diabetes care and that health inequalities may disappear after educational interventions. Thus, interventions specifically targeting these groups of patients may have the potential to reduce social inequalities in health and should be among the priorities of diabetes management programs.
