FIVE-BRANE EFFECTIVE ACTION
IN $M$-THEORY

Edward Witten

Olden Lane, Princeton, NJ 08540, USA

On the world-volume of an $M$-theory five-brane propagates a two-form with self-dual field strength. As this field is non-Lagrangian, there is no obvious framework for determining its partition function. An analogous problem exists in Type IIB superstring theory for the self-dual five-form. The resolution of these problems and definition of the partition function is explained. A more complete analysis of perturbative anomaly cancellation for $M$-theory five-branes is also presented, uncovering some surprising details.

1. Introduction

In a recent paper [1], it was shown that the low energy effective action of $M$-theory on a closed eleven-dimensional spin manifold $Q$ is well-defined. To be more precise, let $I_M$ be the Chern-Simons interaction of the long wavelength limit of $M$-theory; schematically $I_M = CGG + CI_8(R)$, where $C$ is the massless three-form, $G$ is the gauge-invariant field strength of $C$, and $I_8(R)$ is a certain eight-form constructed from the Riemann tensor (first obtained in [2] and [3]). Let $\det D_{R.S.}$ be the path integral of the Rarita-Schwinger field; it is real but not necessarily positive. The long-wavelength limit of the quantum measure of $M$-theory is a product of manifestly well-defined factors times

$$ \det D_{R.S.} e^{iI_M}, $$

and it was shown in [1] that this product is well-defined (though neither factor is well-defined separately). The main novelty required for this result was a gravitational shift in the quantization law of $G$. The shifted quantization law says that

$$ \left[ \frac{G}{2\pi} \right] = \frac{\lambda}{2} + \text{integral cohomology class} \quad (1.2) $$

where $[G/2\pi]$ is the cohomology class of $G/2\pi$, and $\lambda = p_1(X)/2$ ($\lambda$ is integral for a spin-manifold $Q$).

One would like to know whether the long-wavelength effective action is still well-defined in the presence of impurities. There are three known kinds of impurities: boundaries of $Q$ (where $E_8$ supermultiplets are believed to propagate); two-branes; and five-branes. Anomaly cancellation in the presence of boundaries has been demonstrated in [4, 5]. Membrane world-volume anomalies are rather simple because the world-volume theory is non-chiral. The only issues concern the sign of the path integral of the world-volume fermions and the flux quantization law for $G$. There is potentially an anomaly affecting the sign of the fermion determinant, and it was shown in [1] that the $\lambda/2$ term in (1.2) gives an additional effect that cancels this anomaly.

---

2 As in the case of any Majorana fermi field, this path integral might be more naturally called a Pfaffian rather than a determinant.
3 By the quantum measure I mean the exponential of the effective action.
4 To be more precise, perturbative anomaly cancellation was analyzed in those papers; it would be natural to analyze the global anomalies by an extension of ideas in [3].
The remaining case is the five-brane, is the principal subject of the present paper. This case is particularly subtle because the five-brane world-volume theory is chiral. There are therefore potential perturbative anomalies, which have been partially analyzed in and are considered more fully in sections three and five below. One should also consider global anomalies, which can perhaps be treated by an extension of the methods in.

But a question more basic than those will be our main interest here: What is the five-brane partition function? This must be answered before the question of whether this partition function has anomalies can be formulated. The reason that there is a problem is simple. One of the fields on the five-brane world-volume is a self-dual three-form $T$; that is, on the world-volume there is a two-form, say $\beta$, which is constrained so that its field-strength $T$ is self-dual. Such a field, which we will call a chiral two-form, has no Lagrangian formulation, and there is subtlety in defining, even formally, what its partition function should be.

A chiral two-form in six dimensions poses a rather similar problem to a chiral boson $\phi$ in two dimensions (whose field strength is a self-dual one-form $\partial \phi$). In fact, if the world-volume $W$ of the five-brane is of the form $W = \Sigma \times \mathbb{CP}^2$, with $\Sigma$ a Riemann surface, then in the limit that $\Sigma$ is much larger than the $\mathbb{CP}^2$, the theory of the chiral boson on $W$ reduces to the theory of one chiral boson on $\Sigma$. For one chiral boson, there is no modular-invariant partition function — a modular-invariant partition function for chiral bosons requires an even self-dual lattice, and in particular the net number of chiral bosons must be a multiple of eight. So this particular example shows that it is impossible to define for the chiral two-form a partition function that is “modular-invariant,” that is, invariant under arbitrary diffeomorphisms of $W$.

We are not, however, dealing in $M$-theory with a bare six-manifold $W$. $W$ is embedded in an eleven-dimensional spin-manifold $Q$, on which there are fields obeying certain relations such as $dT = G$. In sections two and three, we demonstrate that this additional data is exactly right to make it possible to define a partition function for the chiral two-form, which is invariant (up to an ordinary anomaly) not under all diffeomorphisms of $W$, but under those that preserve the physical data. (By “an ordinary

---

5 Still more generally, but beyond our scope here, one could consider membranes ending on boundaries or five-branes.

6 This particular $W$ is not a spin manifold, but it could be embedded in an eleven-dimensional spin manifold $Q$, and so can arise in $M$-theory.
anomaly,” we mean an anomaly that only affects the phase of the partition function, and so can cancel anomalies coming from other interactions or fields.)

In section four, we make a digression from five-branes, and show that a similar problem arises, and can be treated similarly, for the chiral four-form of Type IIB superstrings – that is, the massless field whose field strength is a self-dual five-form. This problem was avoided in a previous analysis of Type IIB global anomalies [6] by considering only ten-manifolds of vanishing fifth Betti number; for such space-times the problem does not arise, as will be apparent.

Finally, in section five, we look at the ordinary anomalies. To be more precise, we give a more complete analysis of five-brane perturbative anomalies than has been done hitherto. The analysis proves to require some surprising novelty, and we actually get a complete answer only in the Type IIA case, not in M-theory.

My interest in these issues came originally from thinking about non-perturbative superpotentials generated by five-brane instantons [11]. Such an instanton contribution is roughly $e^{-\Phi} P$, where $\Phi$ is a chiral superfield whose real part is the volume of the instanton and $P$ comes from quantum fluctuations. Roughly speaking, zeroes of $P$ determine the supersymmetric vacua. In [11], the zeroes coming from fermion zero modes were analyzed. Additional zeroes can come from the behavior of the partition function of the chiral two-form. To determine the locations of the zeroes requires the considerations of the present paper.

2. Review Of Chiral Scalars In Two Dimensions

2.1. Basic Framework

In this section, we review some aspects of the theory of a chiral scalar in two dimensions, and explain how some of the ideas generalize above two dimensions.

Since there is no effective Lagrangian formulation for a chiral scalar, there is no natural way to use path integrals to determine the partition function. One approach is to take a non-chiral boson, which does have a Lagrangian and a well-defined partition function $Z$, and try to write $Z$ as the absolute value squared of the chiral boson partition function. As is well known, things do not work so simply. $Z$ is not the square of a holomorphic function but a sum of such squares; the number of terms depends on the periodicity or radius of the non-chiral boson.
As will become clear, the radius of relevance to our problem is the free fermion radius. This corresponds to momenta which take values in the unimodular, but not even, one-dimensional lattice $\mathbb{Z}$, endowed with the quadratic form $f(x) = x^2$ (that is, the unit element in $\mathbb{Z}$ is of length one). At the free fermion radius, the partition function of the free boson on a Riemann surface $\Sigma$ of genus $g$ can be written

$$Z = \sum_\alpha |\Theta_\alpha|^2.$$  \hfill (2.1)

Here $\alpha$ runs over the spin structures on $\Sigma$, and $\Theta_\alpha$ is the free fermion partition function with spin structure $\alpha$. In genus one, $\Theta_\alpha = \theta_\alpha/\eta$ where $\theta_\alpha$ is a theta function and $\eta$ is the Dedekind eta function. The functions $\Theta_\alpha$ are the candidate partition functions of the chiral boson. Our problem is to understand – in a form suitable for generalization to five-branes or to Type IIB in ten dimensions – the fact that a choice of spin structure enables one to pick out a particular one of the $\Theta_\alpha$’s.

It is natural to couple the chiral boson to a background gauge field $A$, which we can think of as a connection on a line bundle $\mathcal{T}$. The field strength is then $\Lambda = d\phi + A$, and $\Lambda$ is no longer closed; it obeys $d\Lambda = F$, with $F$ the field strength of $A$. The existence of a gauge-invariant field $\Lambda$ with $d\Lambda = F$ means that (unless we make operator insertions that modify that equation) $c_1(\mathcal{T})$ must vanish, so $\mathcal{T}$ is topologically trivial. Each choice of connection $A$ gives (via the $\bar{\partial}$ operator) a complex structure to $\mathcal{T}$. The moduli space of such complex structures is the Jacobian $J_\Sigma$ of $\Sigma$. One can identify $J_\Sigma$ as $H^1(\Sigma, \mathbb{R})/H^1(\Sigma, \mathbb{Z})$.

The coupling to a background gauge field has an analog in the five-brane problem. The relevant background field here is the three-form $C$ of eleven-dimensional supergravity (restricted to the five-brane world-volume $W$). The field strength of $C$ is $G = dC$. The self-dual three-form $T$ on $W$ obeys $\bar{\partial} dT = G$, and this equation is obviously quite analogous to $d\Lambda = F$. The coupling to $C$ plays for the self-dual three-form a role quite similar to the coupling to a background gauge field for the self-dual one-form. For reasons that will be explained, we will be able to think of $C$ as defining a point in the “intermediate Jacobian” $H^3(W, \mathbb{R})/H^3(W, \mathbb{Z})$.

The equation $dT = G$ means that the restriction of $G$ to the five-brane world-volume $W$ must be zero cohomologically (just as above the relation $d\Lambda = F$ implied that $\mathcal{T}$ is

\footnote{A thorough and direct study of this is in \cite{12}. Note that this problem is much simpler than the generic case of rational conformal field theory in that the space of conformal blocks has a distinguished basis, given by the $\Theta_\alpha$.}
trivial topologically). It follows, therefore, given (1.2), that the restriction of \( \lambda \) to \( W \) is even. This will be important in section three.

**Embedding In Non-Chiral Theory**

We will look now more closely at the embedding of the chiral scalar in the theory of a non-chiral scalar. In doing so, we work on a two-dimensional surface \( \Sigma \) of Euclidean signature, so the Lagrangian will be complex, and the self-duality condition reads \( d\phi = i \ast d\phi \).

We consider thus a scalar field \( \phi \), with a periodicity \( \phi \rightarrow \phi + 2\pi \), and a Lagrangian (at the free fermion radius)

\[
L = \frac{1}{8\pi} \int d^2x (\partial_i \phi) (\partial_j \phi).
\]

We introduce as explained above a \( U(1) \) gauge field \( A \) with gauge transformation law \( \delta A_i = -\partial_i a \), \( \delta \phi = a \), and Lagrangian\(^8\)

\[
L = \frac{1}{8\pi} \int d^2x \sqrt{g} g^{ij} (\partial_i \phi + A_i)(\partial_j \phi + A_j) + \frac{i}{4\pi} \int \Sigma \phi \epsilon^{ij} \partial_i A_j.
\]

(The transformation law of \( \phi \) means that \( \phi \) is a section of the circle bundle on which \( A \) is a connection, which therefore must be topologically trivial as explained earlier in a somewhat different way.) The point of this particular coupling is that \( A \) has been coupled only to the chiral part of \( \phi \). This can be made clear by introducing local complex coordinates \( z, \bar{z} \) (with orientations so that \( \epsilon_z \bar{z} = -\epsilon \bar{z} z = i \)) and expanding the Lagrangian to get

\[
L = \frac{1}{4\pi} \int \Sigma |dz \wedge d\bar{z}| (\partial_z \phi \partial_{\bar{z}} \phi + 2\partial_z \phi A_{\bar{z}} + A_z A_{\bar{z}}).
\]

Thus, only \( A_{\bar{z}} \) and not \( A_z \) couples to the quantum field \( \phi \). It follows that in a suitable sense the partition function

\[
Z(A) = \int D\phi e^{-L}
\]

depends holomorphically on \( A_{\bar{z}} \).

To be more precise, introduce a complex structure on the space of gauge fields in which \( A_{\bar{z}} \) is holomorphic and \( A_z \) is anti-holomorphic. A holomorphic line bundle \( \mathcal{L} \) over

---

\(^8\) A more complete account of the point of view that follows, in the more general context of the WZW model, is in \([13]\).
the space of gauge fields can be defined by taking $\mathcal{L}$ to be the trivial line bundle endowed with the covariant derivatives

$$
\frac{D}{DA_i} = \frac{\delta}{\delta A_i} + \frac{i\epsilon_{ij}^4}{4\pi} A_j.
$$

(2.6)

This means that

$$
\frac{D}{DA_z} = \frac{\delta}{\delta A_z} + \frac{A_z}{4\pi}.
$$

(2.7)

To show that this connection defines a holomorphic structure on $\mathcal{L}$, one must check from (2.6) that

$$
\left[ \frac{D}{DA_z(x)}, \frac{D}{DA_z(x')} \right] = 0.
$$

(2.8)

This is straightforward. Then using the fact that $A_z$ appears in $L$ only in the $A_z A_\bar{z}$ term in (2.4), together with the explicit form of (2.7), one finds that $(D/DA_z)e^{-L} = 0$. The partition function $Z = \int D\phi e^{-L}$ therefore obeys the same equation:

$$
\frac{D}{DA_z} Z = 0.
$$

(2.9)

Thus, the partition function is a holomorphic section of $\mathcal{L}$, over the space of all connections.

The fact that the partition function is most naturally seen as a section of a line bundle rather than a function is related to the fact that the Lagrangian (2.3) is not gauge-invariant. Under gauge transformations $\delta \phi = a, \delta A = -da$, one has

$$
\delta L = \frac{i}{4\pi} \int_\Sigma a \epsilon^{ij} \partial_i A_j.
$$

(2.10)

The partition function thus obeys not standard gauge-invariance, which would read

$$
\partial_i \frac{\delta}{\delta A_i} Z = 0,
$$

(2.11)

but rather

$$
\left( \partial_i \frac{D}{DA_i} - \frac{i\epsilon^{ij} F_{ij}}{4\pi} \right) Z = 0.
$$

(2.12)

This means that the partition function $Z$ is invariant under infinitesimal gauge transformations if interpreted as a section of $\mathcal{L}$ rather than as a function. The operators on the left hand side of (2.12) are the ones that generate infinitesimal gauge transformations when acting on sections of $\mathcal{L}$. This is a special case of a more general assertion about the WZW model; see [13], eqn. (2.17).
So far we have coupled to arbitrary (topologically trivial) background gauge fields $A$. The partition function is constrained by the two conditions of gauge covariance (2.12) and holomorphy (2.9). Taken together, the two conditions determine how the partition function transforms under a complex gauge transformation $\delta A_\tau = -\overline{\partial} \epsilon$, $\delta A_z = -\partial \epsilon$. By a complex gauge transformation one can reduce to $F = 0$. So there is no loss of generality in considering only the coupling to background fields with $F = 0$.

The gauge field $A$, modulo infinitesimal gauge transformations and with $F = 0$, defines a point in $H^1(\Sigma, \mathbb{R})$. With infinitesimal gauge transformations acting as in (2.12), $\mathcal{L}$ descends to a line bundle – which we will also call $\mathcal{L}$ – on $H^1(\Sigma, \mathbb{R})$. $Z$, being gauge invariant in the sense of (2.12), descends to a section of $\mathcal{L}$ over $H^1(\Sigma, \mathbb{R})$. However, we want to also divide by the “big gauge transformations,” and interpret $Z$ as a section of a line bundle over $H^1(\Sigma, \mathbb{R})/H^1(\Sigma, \mathbb{Z})$, which is the Jacobian $J_{\Sigma}$ of $\Sigma$.

There is no natural choice of how the “big gauge transformations” should act on $\mathcal{L}$. Why this is so is explained below. There are in fact different and equally natural line bundles $\mathcal{L}_\alpha$, obtained by differing choices of how the big gauge transformations act on $\mathcal{L}$.

Related to this, the partition function $Z$ considered so far is not really the object we want. It includes the contributions of the “wrong chirality” part of $\phi$ which though decoupled from $A$ is still present in the partition function. If one tries to carry out holomorphic factorization to suppress the wrong chirality field, one finds as in (2.1) that $Z$ is a sum of terms, each involving (as will become clear) a different $\mathcal{L}_\alpha$.

What has been said so far applies to a chiral $2k$-form $\beta$ in $4k + 2$ dimensions for any $k$. The arguments have been presented in such a way that they carry over without any essential change. We repeat the story briefly. Letting $C$ be a background $2k + 1$ form on a $4k + 2$-dimensional manifold $W$, and $G = dC$, consider a non-chiral $2k$-form $\beta$ on $W$, with coupling to $C$ given schematically by $L_\beta = \int_W (|d\beta + C|^2 + \beta \wedge G)$. Choose the coefficients in $L_\beta$ chosen so that only the anti-self-dual part of $C$ couples. The “wrong chirality” part of $\beta$ is thus present, but decoupled. Under infinitesimal gauge transformations $\delta \beta = \alpha$, $\delta C = -d\alpha$, (with $\alpha$ a $2k$-form), $L_\beta$ changes by

$$\delta L_\beta \sim \int_W \alpha \wedge G.$$  

(2.13)

This means that the partition function $Z$ should be understood as a section of a line bundle $\mathcal{L}$ over the space of $C$’s. The fact that only the anti-self-dual part of $C$ couples means that $Z$ is actually a holomorphic section. Holomorphy plus gauge-invariance imply invariance
under complexified gauge transformations, which can be used to reduce to the case that $C$ is a harmonic $2k + 1$-form, defining a point in $H^{2k+1}(W, \mathbb{R})$. The partition function is thus naturally induced from a section of a line bundle over $H^{2k+1}(W, \mathbb{R})$. To define the theory of the chiral two-form, one must carry out holomorphic factorization, throw away the anti-chiral contribution, and divide by “big gauge transformations” so as to descend to $J_W = H^{2k+1}(W, \mathbb{R})/H^{2k+1}(W, \mathbb{Z})$, which is known as the “intermediate Jacobian” of $W$. Holomorphic factorization leads to a sum of different terms, each associated with a different line bundle on $J_W$. The key to finding the partition function of the self-dual scalar is to find a way to pick out a particular term from this sum, or equivalently a particular line bundle on $J_W$.

The Line Bundle

Now let us go back to the free fermion approach to the non-chiral scalar in two dimensions. The factorization (2.1) still holds after coupling to $A$, but now the $\Theta_\alpha$ are functions of $A$ as well as of the complex structure $\tau$ of $\Sigma$.

The $\Theta_\alpha$ can be written as $\Theta_\alpha(\tau, A) = \theta_\alpha(\tau, A)/\tilde{\eta}(\tau)$ where the $\theta_\alpha(\tau, A)$ are theta functions on the Jacobian $J_\Sigma$ (we recall that each $A$ determines a point on $J_\Sigma$) and $\tilde{\eta}(\tau)$ depends only on $\tau$.

Because the coupling of a chiral scalar to a gauge field violates gauge invariance, the partition functions $\Theta_\alpha(\tau, A)$, in their dependence on $A$, are not naturally understood as functions but as sections of appropriate line bundles $L_\alpha$ over the Jacobian. We have essentially seen this already from the bosonic point of view. Moreover – as already indicated – the $\theta_\alpha$ of different $\alpha$ are all sections of different line bundles over $J_\Sigma$. That is the key to our problem. It means that once one finds the line bundle $L_\alpha$ on the Jacobian, a corresponding partition function $\Theta_\alpha$ of the chiral scalar is naturally determined. In fact, each $L_\alpha$ has (up to a complex multiple) only one holomorphic section, as we will see, and so automatically determines its own theta function $\Theta_\alpha$.  

---

9 If $A$ is coupled chirally, as above, the $\Theta_\alpha$ still depend on $\tau$ only; if one uses a vector-like coupling of $A$, the $\Theta_\alpha$ would still be the complex conjugates of the $\Theta_\alpha$.

10 It may appear that the uniqueness (up to an $A$-independent but possibly $\tau$-dependent multiple) of the holomorphic section of $L_\alpha$ determines only the $A$ dependence and not the $\tau$ dependence of the chiral partition function $\Theta_\alpha$. But the partition function $\Theta_\alpha$ obeys a heat equation (a special case of the KZB equation obeyed by the conformal blocks of the WZW model) that determines its $\tau$ dependence when the $A$ dependence is known. The heat equation is a consequence of the

8
the partition function is defined by first finding the right line bundle, may at first sound esoteric, but can be implemented quite uniformly for our three cases: the chiral scalar in two dimensions; the self-dual three-form on the five-brane world-volume; and the self-dual five-form of Type IIB theory in ten dimensions.

2.2. Line Bundles On The Jacobian

Our problem, then, is to study line bundles on the Jacobian \( J_\Sigma \) of a Riemann surface \( \Sigma \), or the intermediate Jacobian \( J_W \) of a \( 4k+2 \)-dimensional manifold \( W \).

To begin with, consider more generally a \( 2n \)-dimensional torus \( J = \mathbb{R}^{2n}/\Gamma \), where \( \Gamma \) is a rank \( 2n \) lattice in \( \mathbb{R}^{2n} \). A “principal polarization” of \( J \) is an element \( \omega \in H^2(J, \mathbb{Z}) \) such that
\[
\int_J \frac{\omega^n}{n!} = 1. \tag{2.14}
\]
\( \omega \) can be represented by a two-form on \( J \) which is uniquely determined if we require it to be invariant under translations of \( J \); this will always be assumed.

An example of such an \( \omega \) is as follows. Let \( x^i, y_j, i, j = 1, \ldots, n \) be coordinates on \( \mathbb{R}^{2n} \) such that \( \Gamma \) is spanned by unit vectors \( e_i \) and \( f^j \) in the \( x^i \) and \( y_j \) directions, respectively. Then \( \omega = \sum_i dx^i \wedge dy_i \) defines a principal polarization. Conversely, any translation-invariant two-form \( \omega \) representing a principal polarization can be put in such a form by a suitable choice of coordinates.

In the example just given, the pairings of the two-form \( \omega \) with the vectors \( e_i \) and \( f^j \) are
\[
\omega(e_i, f^j) = \delta_i^j, \; \omega(e_i, e_j) = \omega(f^i, f^j) = 0. \tag{2.15}
\]
Thus, on the lattice \( \Gamma \), \( \omega \) defines an integer-valued antisymmetric pairing which is non-degenerate and “minimal” (the Pfaffian of \( \omega \) is as small as possible – equivalent to the assertion (2.14) that the volume of a unit cell is 1).

If \( J \) is the intermediate Jacobian of a \( 4k+2 \)-dimensional manifold \( W \) (so \( J = H^{2k+1}(W, \mathbb{R})/H^{2k+1}(W, \mathbb{Z}) \)), then \( \Gamma \) corresponds to the lattice \( H^{2k+1}(W, \mathbb{Z}) \) (mod torsion). The intersection pairing or cup product \( H^{2k+1}(W, \mathbb{Z}) \times H^{2k+1}(W, \mathbb{Z}) \to H^{4k+2}(W, \mathbb{Z}) \cong \mathbb{Z} \)

Sugawara construction: the stress tensor of the chiral boson is the square of the current \( \partial_x \phi + A_x \) that couples to \( A_x \). Likewise, the stress tensor of the chiral \( 2k \)-form is a quadratic expression in the current \( (d\beta + C)^+ \) (the superscript + refers to a projection on the self-dual part), as a result of which there is a heat equation that determines the dependence on the metric of \( W \) from the \( C \) dependence.
defines an integer-valued antisymmetric pairing on $\Gamma$ which is isomorphic to (2.13) in suitable coordinates. (For instance, if $W$ is a Riemann surface, then the intersection pairing on $H^1$ can be put in the form (2.13) by a choice of $A$ and $B$ cycles.) Therefore, the intermediate Jacobians of interest to us are always naturally endowed with a principal polarization. The curvature form $\omega$ associated with this polarization actually can be seen in the curvature of the connection introduced in (2.6).

Given a metric on $W$, the intermediate Jacobian $J_W$ has a natural metric defined as follows. The tangent space to $J_W$ is the space $W$ of harmonic $2k+1$-forms on $W$. The Hodge $*$ operator maps $W \to W$ with $*^2 = -1$, so it defines a complex structure on $J_W$. A metric on $J_W$ can be defined by saying that for $C \in W$, $||C||^2 = \int_W C \wedge * C$. This metric on $J_W$ is translation-invariant and Kahler. The associated Kahler form is our friend the polarization of $J_W$, $\omega(C,C') = \int_W C \wedge C'$. In particular, $\omega$ is of type $(1,1)$ and positive in this Kahler metric.

In fact, the partition function of the chiral $2k$-form only depends on the metric on $J_W$ and the line bundle $L$, up to elementary factors determined by the anomalous Ward identities. This is a striking simplification, as the metric on $W$ (on which the partition function might depend a priori) depends on infinitely many parameters, but the metric on $J_W$, being translation-invariant, depends on only finitely many parameters. This result can be seen using the heat equation described in the footnote at the end of section 2.1: since the stress tensor is quadratic in the “currents,” the response to a change in the metric $W$ can be expressed in terms of the response to a change in the background $C$-field, and just as for a chiral scalar in two dimensions, the only non-elementary terms that arise are those that involve the change in metric of $J_W$ under change in metric of $W$.

**From Polarization To Line Bundle**

Since line bundles are classified topologically by their first Chern class, there is topologically up to isomorphism a unique line bundle $L$ on $J_W$ whose first Chern class is $c_1(L) = \omega$. However, we need to describe $L$ much more precisely. We want to find a $U(1)$ connection $B$ on $L$, whose curvature $F = dB$ equals $2\pi \omega$. This would lead as follows to a definition of the partition function of the chiral $2k$-form. Since $\omega$ is of type $(1,1)$ in the complex structure on $J_W$, the connection $B$ determines a complex structure on $L$. The index of the $\bar{\partial}$ operator on $J$, with values in $L$, is

$$
\sum_{i=0}^{\dim_{C} J_W} (-1)^i \dim H^i(J_W, L) = \int_J e^{c_1(L)} \text{Td}(J_W) = \int_J e^{\omega} = 1. \tag{2.16}
$$
(Here Td is the Todd genus; since \( J_W \) has a flat metric, \( Td(J_W) = 1 \). We also use (2.14).) Since \( \omega \) is positive, the cohomology \( H^i(J_W, L) = 0 \) for \( i > 0 \), so the index formula actually asserts that \( H^0(J_W, L) \) is one-dimensional. Thus, the line bundle \( L \) has (up to a complex multiple) a single holomorphic section. This section is the desired partition function of the chiral \( 2k \)-form, at least as regards the \( C \) dependence. But since the different terms in the holomorphic factorization of the non-chiral \( 2k \)-form have different \( C \) dependence, once we know the \( C \) dependence we are essentially done. (More fundamentally, as remarked in a previous footnote, the \( \tau \)-dependence can be determined once the \( C \)-dependence is known from the fact that the chiral partition function obeys an analog of the KZB equation for conformal blocks of the WZW model.)

So our basic problem is really to find a \( U(1) \) gauge field on \( J_W \) whose curvature is \( F = 2\pi \omega \). Now, on a simply-connected manifold, a \( U(1) \) gauge field \( B \) is determined up to isomorphism by its curvature. We are dealing instead with the torus \( J = \mathbb{R}^{2n}/\Gamma \). (In what follows, \( J \) can be any torus with a principal polarization, as opposed to \( J_W \) which has additional structure such as a metric and complex structure. So we drop the subscript \( W \) for the time being.) To fix \( B \) we must give, in addition to the curvature, the holonomies around noncontractible cycles in \( J \).

If \( a \) is a lattice point in \( \Gamma \subset \mathbb{R}^{2n} \), then the straight line from the origin in \( \mathbb{R}^{2n} \) to \( a \) determines a closed curve \( C(a) \) in \( J \). Let \( H(a) = \exp(i \int_{C(a)} B) \) be the holonomy of \( B \) around \( C(a) \). \( B \) will be completely fixed if the \( H(a) \) are given. We would like to pick the \( H(a) \)'s to preserve, as much as possible, the invariance under the symplectic group \( Sp(2n, \mathbb{Z}) \) (which acts on \( \Gamma \) preserving \( \omega \)). The most obvious choice would be \( H(a) = 1 \) for all \( a \). This is impossible for the following reason.

The \( H(a) \)'s are constrained as follows. If \( a \) and \( b \) are any two lattice points, then

\[
H(a + b) = H(a)H(b)(-1)^{\omega(a,b)}. \tag{2.17}
\]

This is obtained as follows. The lattice points \( 0, a, b, \) and \( a+b \) are vertices of a parallelogram \( \Delta_{a,b} \) through which the magnetic flux is \( 2\pi \omega(a,b) \). The lattice points \( 0, a, \) and \( a+b \) are vertices of a triangle \( T_{a,b} \) which is just half of \( \Delta_{a,b} \); the magnetic flux through \( T_{a,b} \) is \( \pi \omega(a,b) \). The sides of \( T_{a,b} \) are \( C_a, C_b, \) and \( C_{a+b} \). So (2.17) is the usual relation, following

---

11 This is true by the Kodaira vanishing theorem, which uses the fact that \( \overline{\partial} \overline{\partial} + \overline{\partial} \overline{\partial} \) is strictly positive, in this situation, for \( i > 0 \).
from Stokes’s theorem, between the magnetic flux through a surface $S$ – in this case $T_{a,b}$ – and the holonomy around the boundary of $S$.

A basic question is now whether it is possible to pick a line bundle in a way invariant under the $Sp(2n;\mathbb{Z})$ that acts on $J$ preserving the polarization. (2.17) shows that this is impossible; $Sp(2n;\mathbb{Z})$ would require that $H(a) = H(b)$ for all primitive lattice vectors $a$ and $b$, and this is incompatible with (2.17). In particular, (2.17) does not permit us to take $H(a) = 1$ for all $a$. (2.17) does, however, allow $H(a)^2 = 1$ for all $a$. The numbers $H(a)^2$ would be the holonomies around $C_a$ of the connection $2B$ on the line bundle $L^2$, which we will call $\mathcal{M}$. Thus, there is a completely natural, $Sp(2n,\mathbb{Z})$-invariant line bundle $\mathcal{M}$ with holonomy +1 around each $C_a$ and first Chern class $2\omega$. The factor of 2 means that (using the index formula as above) $H^0(J, \mathcal{M})$ is of dimension $2^g$. We need a line bundle $L$ of first Chern class $1 \cdot \omega$, with just one holomorphic section, which will be our partition function.

In searching for an $L$ that is “as canonical as possible,” we can require that $L^2$ is isomorphic to $\mathcal{M}$, or equivalently that the holonomies $H(a)$ of $L$ are all $\pm 1$. The number of such $L$’s is $2^{2n}$; they differ by $H(a) \rightarrow H(a)(-1)^{\epsilon(a)}$ with $\epsilon \in H^1(J, \mathbb{Z}_2)$. Thus, the search for $L$ is reduced to the selection among a finite set of possibilities.

In case $J = J_{\Sigma}$ is the Jacobian of a Riemann surface $\Sigma$, we already know from bose-fermi equivalence (that is, from the holomorphic factorization of the free boson at the free-fermion radius) that to pick an $L$ out of the $2^{2n}$ possibilities, what we need is precisely a spin structure on $\Sigma$. In the remainder of this section, I will sketch three direct explanations of this fact. The first two, though not needed in the rest of the paper (and therefore not explained below in much detail), are included because they are short and illuminating. The third explanation, though not new [14], is perhaps less well-known. It is this third approach that we will later generalize above two dimensions.

The Determinant Bundle

The first approach is directly related to the free fermion construction of the chiral boson. If we are given a spin structure $\alpha$ on $\Sigma$, then we can use the determinant of the Dirac operator to obtain a line bundle on $J_{\Sigma}$.

---

12 There is one significant exception; if $J$ is two-dimensional then (2.17) allows $H(a) = -1$ for all primitive $a$. This corresponds to the fact that on (and only on) a genus one curve, there is a spin structure that is completely diffeormorphism-invariant, namely the “odd” one (the trivial spin bundle). For dim $J > 2$, the possibility $H(a) = -1$ for all primitive $a$ is excluded as one can find vectors $a, b$ with $a, b$, and $a + b$ all primitive and $\omega(a, b) = 0$. 

12
Thus, given a flat connection $A$ on $\Sigma$ representing a point in $J_\Sigma$, let $T_A$ be the corresponding flat line bundle on $\Sigma$. Let $D_\alpha(A)$ be the Dirac operator with values in $T_A$, using the spin structure $\alpha$. The determinant line of $D_\alpha(A)$ is a complex line $L_{\alpha,A}$, and these fit together as $A$ varies to give the desired line bundle $L_\alpha \to J_\Sigma$, which can be shown via index theory to have the right first Chern class. It thus has a single holomorphic section, which is in fact the function $\Theta_\alpha$ that appears in holomorphic factorization of the non-chiral boson.

So in particular, a choice of spin structure on $\Sigma$ gives a choice of line bundle on $J_\Sigma$. Of course, the discussion has now brought us back to our starting point (2.1), and if we were interested only in the two-dimensional case we could have spared much of our effort.

**The Shifted Jacobian**

Now we consider briefly another approach which is less obviously related to physics. We consider the shifted Jacobian $J_{\Sigma,n}$ of $\Sigma$, which parametrizes holomorphic line bundles on $\Sigma$ of degree $n$. They are all non-canonically isomorphic to the ordinary Jacobian $J_\Sigma$. Fixing a line bundle $S$ of degree $n$, the map $T \to T \otimes S$ (where $T$ is a line bundle of degree zero, defining a point in $J_\Sigma$, and $T \otimes S$ therefore has degree $n$ and defines a point in $J_{\Sigma,n}$) is an isomorphism between $J_\Sigma$ and $J_{\Sigma,n}$. In particular, the existence of this isomorphism means that each $J_{\Sigma,n}$ is naturally endowed with a principal polarization $\omega$.

On $J_{\Sigma,g-1}$, there is actually a completely natural (“modular-invariant”) choice of line bundle with first Chern class $\omega$; we call it $L'$ to distinguish it from the desired line bundle $L$ on $\Sigma$. In fact, a line bundle on a complex manifold can be given by specifying a divisor. On $J_{\Sigma,g-1}$, there is a natural divisor, the $\Theta$ divisor, that parametrizes line bundles with a holomorphic section. It can be shown that the associated line bundle $L'$ on $J_{\Sigma,g-1}$ has first Chern class $\omega$.

Now if $S$ is any line bundle on $\Sigma$ of degree $g-1$, then by using $S$ as explained above to establish an isomorphism between $J_\Sigma$ and $J_{\Sigma,g-1}$, we can interpret $L'$ as a line bundle on $J_\Sigma$. Thus, to find the desired line bundle on $J_\Sigma$ all we need to do is to pick an $S$. There

---

13 An important subtlety, which is the reason that one must here use the Dirac operator rather than the $\overline{\partial}$ operator (which does not require a choice of spin structure) is that because $D_\alpha(T_A)$ has zero index, $L_A$ depends in an appropriate sense only on the isomorphism class of $T_A$. That is essential because without making any arbitrary choices, $J_\Sigma$ parametrizes a family of isomorphism classes of line bundles on $\Sigma$, but non-modular-invariant choices are needed to get an actual family of line bundles.
is no natural choice of $S$. The closest one can come is to set $S$ equal to one of the $2^{2g}$ spin structures of $\Sigma$. (Recall that a spin structure on $\Sigma$ corresponds to a line bundle of degree $g - 1$ whose square is isomorphic to the canonical line bundle; there are $2^{2g}$ of them, and they are on the smallest possible orbit of the modular group in $J_{\Sigma, g-1}$.) So we get again the expected result: any choice of spin structure gives a choice of line bundle $\mathcal{L}$ on $J_\Sigma$ with first Chern class $\omega$.

**Chern-Simons Theory**

Finally, we come to the approach that we will actually use in the rest of this paper, in generalizing above two dimensions. To construct the desired line bundle on the Jacobian of a two-dimensional surface, we use the Chern-Simons functional of a gauge field in three dimensions.

Let $M$ be a closed oriented three-manifold, and let $A$ be a connection on a $U(1)$ bundle $\mathcal{T}$ over $M$. If $\mathcal{T}$ is topologically trivial, so that in a given gauge $A$ is an ordinary one-form, the Chern-Simons functional is

$$I(A) = \frac{1}{2\pi} \int_M \epsilon^{ijk} A_i \partial_j A_k.$$  

(2.18)

If $\mathcal{T}$ is topologically non-trivial, a more powerful approach to defining $I$ is needed. Let $X$ be an oriented four-manifold with boundary $M$, over which $A$ and $\mathcal{T}$ extend, and pick such an extension.\(^{14}\) (We assume that the orientation of $X$ is related to that of $M$ by a definite convention, for instance “outward normal first.” We will abbreviate the statement that $X$ has boundary $M$ and $(A, \mathcal{T})$ have been extended over $X$ by saying that $X$ has boundary $(M, A)$.) Then define

$$I_X(A) = \frac{1}{2\pi} \int_X \epsilon^{ijkl} \partial_i A_j \partial_k A_l = \frac{1}{8\pi} \int_X \epsilon^{ijkl} F_{ij} F_{kl}.$$  

(2.19)

\(^{14}\) Since line bundles are classified by maps to $\mathbb{CP}^\infty$, the existence of such an $X$ follows from the statement that the oriented bordism group $\Omega_3(\mathbb{CP}^\infty)$ vanishes. In fact, a more precise statement (which we will need presently) also holds: the spin bordism group $\Omega_3(\mathbb{CP}^\infty)$ vanishes. (This means that if $M$ is a spin manifold with a given spin structure, one can choose $X$ with boundary $M$ so that $A$ and the spin structure of $M$ extends over $X$.) The following proof of this was sketched by P. Landweber. According to the proposition on p. 354 of \cite{15}, $\Omega_3(\mathbb{CP}^\infty) = \Omega_5^{Spin^c}$. According to the theorem on p. 337 of the same book, since there are no rational characteristic numbers in odd dimensions, $\Omega_5^{Spin^c}$ is determined by Stieffel-Whitney numbers. A $Spin^c$ manifold has $w_1 = w_3 = 0$. A five-dimensional manifold with $w_1 = 0$ has $w_5 = 0$. So a five-dimensional $Spin^c$ manifold has no non-zero Stieffel-Whitney numbers, and hence $\Omega_5^{Spin^c} = 0$. 

14
The point of this definition is, first of all, that if $\mathcal{T}$ is trivial and $A$ is well-defined as a one-form, then by Stokes’s theorem, $I_X(A)$ coincides with $I(A)$ as defined in (2.18). Furthermore, $I_X(A)$ is defined even if $\mathcal{T}$ is topologically non-trivial. What remains is to investigate the extent to which $I_X(A)$ depends on the choice of $X$ (and the extension of $A$ and $\mathcal{T}$). Given another oriented four-manifold $X'$ with boundary $(M, A)$, one can glue $X$ and $X'$ together along their common boundary to make a closed four-manifold $Y$ with a $U(1)$ gauge field $A$; if we reverse the orientation of $X'$, then the orientations of $X$ and $X'$ match along their common boundary, so that $Y$ has a natural orientation. Then $I_X(A) - I_{X'}(A) = I_Y(A)$, where

$$I_Y(A) = \frac{1}{8\pi} \int_Y \epsilon^{ijkl} F_{ij} F_{kl}. \tag{2.20}$$

The point is now that because the cohomology class $[F/2\pi]$ is integral, $I_Y(A) = 2\pi \cdot \text{integer}$. Hence $I_X(A)$ is independent of $X$ modulo $2\pi\mathbb{Z}$; with the understanding that there is this $2\pi\mathbb{Z}$ ambiguity, we henceforth drop the subscript $X$ and refer simply to $I(A)$.

The fact that $I(A)$ is well-defined modulo $2\pi$ means that

$$e^{iI(A)} \tag{2.21}$$

is well-defined. $U(1)$ Chern-Simons gauge theory at level one is in fact defined by the path integral

$$\int DA \ e^{iI(A)}. \tag{2.22}$$

If one considers $M$ to be not a closed three-manifold, but rather $M = \Sigma \times \mathbb{R}$ where $\Sigma$ is a Riemann surface and $\mathbb{R}$ parametrizes “time,” then the moduli space of classical solutions of the Chern-Simons theory is the Jacobian $J_\Sigma$ (since the equation for a critical point of $I(A)$ is $F = 0$). The quantum Hilbert space is a space of sections of a certain line bundle $\mathcal{M}$ over $J_\Sigma$. $\mathcal{M}$ is roughly the sort of object that we are looking for. However, since the construction is completely diffeomorphism-invariant and in particular no choice of spin structure has entered, $\mathcal{M}$ is modular-invariant and therefore cannot be the desired line bundle with first Chern class $\omega$. $\mathcal{M}$ is in fact, as we will see, the modular-invariant line bundle with first Chern class $2\omega$ (and all $H(a) = 1$) that was seen before.

To better understand $\mathcal{M}$, a first orientation is as follows. Let $\Sigma$ be a Riemann surface and let $N$ be a three-manifold with boundary $\Sigma$. Let $A$ be a connection on a line bundle $\mathcal{T}$ over $N$, and consider the (level one) Chern-Simons Lagrangian

$$L_{C.S.} = -iI(A) = -\frac{i}{2\pi} \int_N \epsilon^{ijk} A_i \partial_j A_k. \tag{2.23}$$

15
In proving gauge-invariance, one must integrate by parts, and one picks up a non-zero surface term because $N$ has a non-empty boundary. In fact, under $\delta A_i = -\partial_i a$, one finds

$$\delta L_{C.S.} = \frac{i}{2\pi} \int_{\Sigma} a \epsilon^{ij} \partial_i A_j.$$  

(2.24)

Just as in our discussion of the chiral boson, this violation of gauge invariance means that $e^{-L_{C.S.}} = e^{iI(A)}$ is most naturally understood not as a function but as a section of a line bundle $M$ over the space of gauge fields on $\Sigma$. In fact, the right hand side of (2.24) has the same form as (2.10), but the coefficient is twice as large; the factor of two means that $M$ is not the desired line bundle $\mathcal{L}$ for the theory of the chiral boson, but rather $M = \mathcal{L}^2$, as we will show more fully later.

Let us describe more precisely the construction of $M$. First I sketch a rather down-to-earth approach. To describe up to isomorphism a line bundle $M$, with $U(1)$ connection, on any given manifold $Z$, it suffices to define the holonomies of the connection around an arbitrary loop in $Z$; these must obey certain axioms that will be discussed. In our case, $Z$ is the space of $U(1)$ gauge fields on $\Sigma$. Suppose we are given a loop $C$ in the space of gauge fields, that is to say a family of gauge fields on $\Sigma$ depending on an extra parameter $\theta$ ($0 \leq \theta \leq 2\pi$); $\theta$ parametrizes the position on $C$. Making the $\theta$ dependence explicit, we write $A_i(x; \theta)$ for this family of gauge fields, where $x$ is a point in $\Sigma$. Now on the three-manifold $\Sigma \times S^1$, we introduce the gauge field $A_C$ whose component in the $S^1$ (or $\theta$) direction is zero, and whose components along $\Sigma$ are $A_i(x; \theta)$. We define the holonomy of $M$ around the loop $C$ to be

$$H(C) = e^{iI(A_C)}.$$  

(2.25)

The property of the $H(C)$’s that is needed for them to be the holonomies of a connection on a line bundle $M$ is the following. If $C_1$ and $C_2$ are two loops in $Z$ that meet at a point $p \in Z$, and $C_1 \ast C_2$ is the loop made by “joining” $C_1$ and $C_2$ at $p$, one wishes

$$H(C_1 \ast C_2) = H(C_1)H(C_2).$$  

(2.26)

In the present case, this is proved as follows. Let $D$ be a “pair of pants” with three boundaries that we associate with $C_1$, $C_2$, and $-C_1 \ast C_2$. (The minus sign refers to a reversal of orientation.) Then the desired relation

$$e^{iI(A_C_1 \ast C_2)} = e^{iI(A_{C_1})}e^{iI(A_{C_2})}$$

(2.27)
follows from the definition (2.19) applied to the four-manifold \( X = \Sigma \times D \) whose boundary is the union of \( X \times C_1, X \times C_2, \) and \(-X \times C_1 \ast C_2.\)

One can verify directly from the definition (2.25) that if \( C \) is a straight line on the Jacobian from the origin to any point \( a \in H^1(\Sigma, \mathbb{Z}) \) (which we represent by a harmonic one-form of the same name), then \( H(C) = 1.\) This is done by first finding an oriented three-manifold \( B, \) of boundary \( \Sigma, \) over which \( a \) extends as a closed but no longer harmonic one-form with integral periods. \((B \) can have very simple topology; it can be a “handlebody.”\)

Over the four-manifold \( X = B \times S^1, \) the gauge field \( A_C \) extends in a fairly obvious way \((\text{as a } \theta \text{-dependent multiple of } a, \text{ with again } \theta \text{ parametrizing the position on } S^1), \) so that \( F \wedge F = 0 \) pointwise, and therefore \( I_X(A) = 0. \) So as promised several times, \( \mathcal{M} \) is our friend, the modular-invariant line bundle with all \( H(a) = 1.\)

The foregoing constructs an isomorphism class of line bundles \( \mathcal{M} \) but not an actual \( \mathcal{M}. \) If one is interested in “seeing” an actual \( \mathcal{M} \) as precisely as possible, one may use the following somewhat abstract approach (for full details and a number of variants see \([16-18]\)). Given a \( U(1) \) gauge field \( A \) on \( \Sigma, \) we must construct a one-dimensional complex vector space \( \mathcal{M}_A, \) in such a way that the \( \mathcal{M}_A \) vary nicely with \( A, \) as fibers of a complex line bundle \( \mathcal{M}. \) We simply declare that if \( N \) is any three-manifold with boundary \( \Sigma \) over which \( A \) extends -- that is if \( N \) has boundary \( (\Sigma, A) \) -- then \( \mathcal{M}_A \) has a basis vector \( \psi_A(N). \) Given two possible \( N \)'s, say \( N_1 \) and \( N_2, \) we must now exhibit a linear relation between \( \psi_A(N_1) \) and \( \psi_A(N_2). \) This linear relation is chosen to be as follows. Let \( P \) be the oriented three-manifold obtained by gluing \( N_1 \) and \( N_2 \) together (with opposite orientation for \( N_2 \) along their common boundary. Let \( A_P \) be the connection (on a line bundle over \( P \)) made by combining the chosen extensions of \( A \) over \( N_1 \) and \( N_2. \) The relation between \( \psi_A(N_1) \) and \( \psi_A(N_2) \) is then chosen to be

\[ \psi_A(N_1) = e^{iI(A_P)}\psi_A(N_2). \]

(2.28)

Given many \( N_i \)'s, one would construct three-manifolds \( P_{ij} \) by gluing \( N_i \) to \( N_j, \) and set \( \psi_A(N_i) = e^{iI(A_{P_{ij}})}\psi_A(N_j); \) these relations can be shown to be compatible using the definition (2.19) of the Chern-Simons functional. Armed with these relations, the \( \psi_A(N_i) \) can

\[ \text{If } A \text{ is a connection on a topologically non-trivial line bundle } \mathcal{T} \text{ over } \Sigma, \text{ then such an } N \text{ does not exist. Instead one fixes a Riemann surface } \Sigma_0 \text{ with a line bundle } \mathcal{T}_0 \text{ of the same first Chern class as } \mathcal{T} \to \Sigma, \text{ and takes } N \text{ to be a bordism between } \Sigma \text{ and } \Sigma_0 \text{ (extending the line bundles and connection). The rest of the construction proceeds as in the text.} \]
be interpreted as vectors in a common one-dimensional space $T_A$, which is the desired fiber of $T$ over the connection $A$. For a description of the connection on $T$ and explanation of its properties, consult the references.

**Chern-Simons Theory At Level One Half**

Now it is clear what we need in order to get a line bundle whose first Chern class will be $\omega$ instead of $2\omega$. We must consider Chern-Simons theory at level one-half.

In other words, consider the functional

$$\frac{I(A)}{2} = \frac{1}{16\pi} \int_X \epsilon^{ijkl} F_{ij} F_{kl},$$

(2.29)

where $A$ is a gauge field on an oriented three-manifold $M$, and $X$ is an oriented four-manifold, of boundary $M$, over which $A$ has been extended. If $I(A)/2$ were well-defined (independent of the choice of $X$) modulo $2\pi$, then by using everywhere $e^{iI(A)/2}$ instead of $e^{iI(A)}$ in the above construction, we would get the desired line bundle of first Chern class $\omega$.

The problem is that, for a closed four-manifold $Y$, the integral

$$\frac{1}{16\pi} \int_Y \epsilon^{ijkl} F_{ij} F_{kl}$$

(2.30)

is an arbitrary integer multiple of $\pi$, but not necessarily an even integer multiple of $\pi$. This comes from the following. Let $x$ be the cohomology class $[F/2\pi]$. Then the integral in (2.30) can be interpreted as $\pi x^2$. In general, the class $x$ is integral, so $x^2$ is integral, but subject to no other general restrictions.

Suppose, however, that $Y$ is a spin manifold. If so, the intersection form on $H^2(Y, \mathbb{Z})$ is even: for arbitrary $x \in H^2(Y, \mathbb{Z})$, $x^2$ is an even integer. This is just what we need. If we may assume that the four-manifolds $Y$ in (2.30) are always spin, then (2.30) would indeed always be an integral multiple of $2\pi$.

If one wants to encounter only four-manifolds with spin structure, one must begin by only considering three-manifolds with a chosen spin structure. Thus, let $M$ be an oriented three-manifold with a chosen spin structure. Given a $U(1)$ gauge field $A$ over $M$, we would like to define $I(A)/2$. (The definition will in general depend on the spin structure of $M$.) The definition is made by the formula (2.29), where $X$ is an arbitrary oriented four-manifold of boundary $M$, to which $A$ and the spin structure of $M$ extend. (A proof that such $X$’s exist was sketched in a previous footnote.) Any two such $X$’s will glue
together to make a spin-manifold $Y$, for which (2.30) will be an integral multiple of $2\pi$. Therefore, if $I(A)/2$ is defined using only $X$’s of the indicated type, then the definition of $I(A)/2$ in (2.29) is independent of the choice of $X$ modulo $2\pi$.

Now let us tidy up a few details and solve our problem. We are given a Riemann surface $\Sigma$ with a spin structure $\alpha$. We want to find a line bundle $L_\alpha$ over the Jacobian $J\Sigma$, with a connection, compatible with the polarization of $J\Sigma$. Given a loop $C$ in the space of connections on $\Sigma$, we build (as above) the associated gauge field $A_C = A_i(x;\theta)$ on the three-manifold $M = \Sigma \times S^1$. We give $M$ the spin structure which is the product of the spin structure $\alpha$ on $\Sigma$ with the “Neveu-Schwarz” spin structure on $S^1$ (this is the “antiperiodic” spin structure, the one which arises if $S^1$ is regarded as the boundary of a disc). We then characterize $L$ by declaring its holonomy around $C$ to be

$$H(C) = e^{iI(A_C)/2}. \quad (2.31)$$

The need to use the antiperiodic spin structure on $S^1$ emerges when one tries to prove that $H(C_1)H(C_2) = H(C_1 * C_2)$. The proof of this involves the four-manifold $\Sigma \times D$, where $D$ is a “pair of pants” (with $C_1$, $C_2$, and $-C_1 * C_2$ on the boundary). The reason that one must use the antiperiodic spin structure on the boundary components is that (i) one needs to use the same spin structure on each boundary component, to treat them all symmetrically (or the $H(C)$’s will not obey the appropriate factorization); (ii) the spin structure on the boundary of $D$ must extend over $D$. The two conditions together are satisfied precisely if the spin structure on the boundary is antiperiodic.

**A Note On Bordism**

Happily, this is the end of the story for the chiral boson, at least for the present paper. But with an eye to generalizations, we will say a word about how bordism really enters the construction.

The above recipe for defining the line bundles $L_\alpha$ used the fact that if $M$ is a spin three-manifold with line bundle $\mathcal{T}$, then there is a four-manifold $X$, with boundary $M$, over which the spin structure of $M$ and the line bundle $\mathcal{T}$ extend. This is described mathematically by saying that $\Omega^{\text{spin}}_3(\mathbb{C}P^\infty) = 0$, a fact discussed in a previous footnote.

What would we say instead if $\Omega^{\text{spin}}_3(\mathbb{C}P^\infty)$ were non-zero? To make the discussion definite, suppose that $\Omega^{\text{spin}}_3(\mathbb{C}P^\infty)$ were $\mathbb{Z}_2$. Pick a three-manifold $M_0$ with a $U(1)$ gauge field $A_0$ such that the pair $(M_0, A_0)$ represents the non-zero element of $\Omega^{\text{spin}}_3(\mathbb{C}P^\infty)$. There is then no natural way to define $I(A_0)/2$, since no appropriate $X$ exists for the definition.
However, if $\Omega^{spin}_3(\mathbb{CP}^\infty) = \mathbb{Z}_2$, then there exists an $X$ whose boundary is two copies of $(M_0, A_0)$. By using this $X$ in (2.29), we can define $w = 2 \cdot I(A_0)/2$. There are now two candidates (namely $w/2$ and $\pi + w/2$) for what $I(A_0)/2$ should be. Pick one of them.

Once $I(A_0)/2$ has been defined, one can define $I(A)/2$ for any $U(1)$ gauge field $A$ on a three-manifold $M$. In fact, the pair $(M, A)$ is either the boundary of some $X$ or is bordant to $(M_0, A_0)$ via some $X$ (that is, there is an $X$ whose boundary is either $(M, A)$ or $(M, A) - (M_0, A_0)$, where the minus sign represents a reversal of orientation). Taking the integral in (2.29) to define either $I(A)/2$ or $I(A)/2 - I(A_0)/2$ as the case may be, we get (since $I(A_0)/2$ has already been defined) a general definition of $I(A)/2$. This definition can be used to define the line bundle $\mathcal{L}_\alpha \to J_\Sigma$ for every spin surface $(\Sigma, \alpha)$. The definition is invariant under $\alpha$-preserving diffeomorphisms of $\Sigma$, but will depend on the choice that was made in defining $I(A_0)/2$. Thus, we get a definition of the $\mathcal{L}_\alpha$’s that is diffeomorphism-invariant to the expected extent, but depends on a $\Sigma$-independent choice in the definition of $I(A_0)/2$. This choice is roughly analogous to the choice of a discrete theta angle.

The generalization from $\mathbb{Z}_2$ to an arbitrary group is easy to state. Let $H = \text{Hom}(\Omega^{spin}_3(\mathbb{CP}^\infty), U(1))$. Then $H$ classifies the possible definitions of $I(A)/2$, and thus the possible recipes for the association $(\Sigma, \alpha) \to \mathcal{L}_\alpha$. The sort of “discrete theta angle” that has just been described will turn out not to appear for five-branes – as the relevant bordism group is zero – but may appear in other, similar examples.

### 3. Chiral Two-Form On Five-Brane World-Volume

In this section, we will use a differential form notation to avoid a proliferation of unilluminating constants. For instance, if $M$ is a three-manifold with $U(1)$ gauge field $A$, and $X$ is a four-manifold with boundary $(M, A)$, we write $x = F/2\pi$, and we define the Chern-Simons functional simply as

$$I(A) = 2\pi \int_X x \wedge x.$$  \hspace{1cm} (3.1)

This is aimed to make it clear that – as $\int_X x \wedge x$ would be an integer for $X$ a closed four-manifold – $I(A)$ is well-defined with values in $\mathbb{R}/2\pi\mathbb{Z}$. We also will omit wedge products and write $x^2$ for $x \wedge x$. 
Now, consider a chiral two-form $\beta$ on a six-manifold $W$. First we consider $W$ in isolation; then we consider a more general case – relevant to M-theory – in which $W$ is embedded in an eleven-dimensional spin manifold $Q$, satisfying certain physical conditions.

We know from section two that to study the chiral two-form, we should introduce the intermediate Jacobian $J_W$ of $W$. This carries a natural polarization $\omega \in H^2(J_W, \mathbb{Z})$, and we must find a line bundle on $J_W$ whose first Chern class is $\omega$. The partition function of the chiral two-form is then uniquely determined.

We also know that to find a line bundle on $J_W$, we should consider Chern-Simons theory in seven dimensions. Let then $M$ be a seven-manifold with a three-form field $C$. Actually, the field $C$ we want is not a three-form in the standard sense. The field strength $G = dC$ is allowed to have $2\pi$ periods (this statement will soon receive a slight modification), and the gauge transformations $C \rightarrow C + d\epsilon$ ($\epsilon$ a two-form) are to be supplemented by “big” gauge transformations adding to $C$ a closed three-form with $2\pi$ periods. The relation of $C$ to a conventional three-form is just like the relation of a $U(1)$ gauge field to a conventional one-form. Anyway, given such a $C$, we want to define the Chern-Simons functional $I(C)$. This is done in a fashion that should be familiar. Let $X$ be an oriented eight-manifold with boundary $M$ over which $C$ extends. We describe this in brief by saying that $X$ has boundary $(M, C)$. Let $x = G/2\pi$. The Chern-Simons functional is then

$$I(C) = 2\pi \int_X x^2. \quad (3.2)$$

This definition makes it clear that $I(C)$ is well-defined modulo $2\pi$. Therefore, $I(C)$ can be used exactly as in section two to define a line bundle $\mathcal{M}$ over the intermediate Jacobian $J_W$ of a six-manifold. However, since the construction is completely diffeomorphism-invariant, $\mathcal{M}$ can hardly be the line bundle we want. In fact, rather as for the chiral scalar in two dimensions, $\mathcal{M}$ is the line bundle of first Chern class $2\omega$ and holonomy one around every straight line in $J_W$.

To make progress, we must define $I(C)/2$ modulo $2\pi$. Then the Chern-Simons construction of line bundles, starting with $I(C)/2$, will give the right line bundle.

---

16 Existence of such an $X$ depends on whether the pair $(M, G)$ vanishes in $\Omega_7(K(\mathbb{Z}, 4))$ (which classifies bordism classes of seven-manifolds with a four-dimensional cohomology class). I do not know if that group vanishes; if not, the considerations raised at the end of section two will enter. But presently we will put a spin condition on $M$, and then the relevant bordism group becomes $\Omega_7^{\text{spin}}(K(\mathbb{Z}, 4))$, which does vanish by a result of Stong [19].
To define $I(C)/2$ modulo $2\pi$, some additional structure is needed. Recalling the case of the chiral scalar, and with an eye on physics, in which spinors are present, one’s first thought is to assume that $M$ is a spin manifold with a chosen spin structure (and restrict $X$ so that the spin structure of $M$ extends over $X$ – such an $X$ exists as noted in the last footnote). If it were the case that the intersection form on $H^4(X, \mathbb{Z})$, for an eight-dimensional spin manifold $X$, were always even, our problem would be solved. The even-ness of $x^2$ in the spin case would give a factor of two in (1.2), so that $I(C)/2$ would be well-defined modulo $2\pi$.

It is, however, not true that the intersection form on the middle-dimensional cohomology of an eight-dimensional spin manifold is even. Indeed, the quaternionic projective space $\mathbb{HP}^2$ is a simple counterexample. ($H^4(\mathbb{HP}^2, \mathbb{Z}) = \mathbb{Z}$, and the intersection form is the unimodular, but not even, form with $f(x) = x^2$.) Instead there is the following relation. Let $p_1$ be the first Pontryagin class of $X$. In any dimension, there is a canonical way to divide the first Pontryagin class of a spin manifold by two to get an integral class that we will call $\lambda$. Then for any $v \in H^4(X, \mathbb{Z})$,

$$v^2 = v \cdot \lambda \mod 2. \tag{3.3}$$

(A proof of this using $E_8$ index theory is at the end of section four of [1].) This can be rewritten as the statement that

$$\frac{1}{2} \int_X \left( \left( v - \frac{\lambda}{2} \right)^2 - \frac{\lambda^2}{4} \right) \in \mathbb{Z}. \tag{3.4}$$

This suggests that we should be the following. Instead of asking that $G/2\pi$ should be integral, we require

$$\left[ \frac{G}{2\pi} \right] = \frac{\lambda}{2} - v, \tag{3.5}$$

with $v$ an integral class. This is in fact the correct quantization law for $G$ in $M$-theory [1]. Then, with $x$ still denoting $G/2\pi$, we modify the definition of $I(C)$ slightly and take

$$\frac{\tilde{I}(C)}{2} = \pi \int_X \left( x^2 - \frac{\lambda^2}{4} \right). \tag{3.6}$$

Since $x = \lambda/2 - v$ with integral $v$, it follows from (3.4) that $\tilde{I}(C)/2$ is well-defined modulo $2\pi$ and so can be used to define a line bundle $\mathcal{L}$ (just as we would have done with $I(C)/2$ had that been well-defined modulo $2\pi$ on the original class of $G$’s).
As we have divided by two, $\mathcal{L}$ has the desired first Chern class, $c_1(\mathcal{L}) = \omega$. We do have to be a little careful in describing where $\mathcal{L}$ is defined. Because the quantization law of $G$ has been shifted, $G = 0$ may not be allowed. To be more precise, (3.5) permits $G = 0$ precisely if $\lambda$ is even. If $\lambda$ is not even, the above construction gives a line bundle $\mathcal{L}$ not on the intermediate Jacobian $J_W$ but on a shifted version of it with $G/2\pi$ congruent to $\lambda/2$ modulo integral classes.

In the application to $M$-theory, with $W$ understood as the world-volume of a five-brane, one can assume (because of the world-volume equation $dT = G$) that the restriction of $G$ to $W$ has vanishing cohomology class. (And (3.5) means therefore that the restriction of $\lambda$ to $W$ must be even.) In this situation, it is the ordinary, unshifted intermediate Jacobian $J_W$ on which the above construction gives a line bundle.

The main point is that as the correction to quantization of $G$ needed to define $\tilde{I}(C)/2$ is the same as the one that appears in the physics, the line bundle appears precisely in the right place.

3.1. Embedding In Eleven Dimensions

So far, we have considered the chiral two-form on a “bare” six-dimensional spin manifold $W$.

We are really interested in an $M$-theory application in which $W$ is a six-dimensional submanifold of an eleven-manifold $Q$. Moreover, $W$, though oriented, is not necessarily spin; it is $Q$ that carries a spin structure.

We will assume for simplicity that $W$ is compact. More general cases, in which for instance $W$ is asymptotically flat, are also natural; in such cases, some knowledge of what is happening at infinity can serve as a substitute for compactness.

The discussion in the last subsection was adequate if the normal bundle to $W$ in $Q$ is trivial – that is if $Q$ looks locally near $W$ like $W \times \mathbb{R}^5$. If so, the normal directions can be decoupled from the discussion and what we are about to say reduces to what was said above.

The first question we might want to ask is how to achieve gauge-invariance even locally for the three-form field $C$ of $M$-theory. We recall that $C$ is coupled to the chiral two-form
on the five-brane, and that this coupling is not invariant under gauge transformations
\[ \delta C = -d\alpha \] of the \( C \)-field. The failure of gauge invariance was described in (2.13):
\[ \delta L_{\text{eff}} \sim \int_Q \alpha \wedge G. \] (3.7)

The numerical coefficient multiplying the right hand side can be most usefully described as follows. Suppose that \( W \) is the boundary of a seven-manifold \( M \). Let \( I(C) \) be the seven-dimensional Chern-Simons functional defined in (3.2). It is gauge-invariant on a closed seven-manifold, but not on a seven-manifold with boundary. In fact,
\[ \delta L_{\text{eff}} = \frac{1}{2} \delta I(C). \] (3.8)

This factor of one-half is the reason that in the discussion above it was necessary to define a version of \( I(C)/2 \). Upon taking \( W = \Sigma \times \mathbb{CP}^2 \), with \( \Sigma \) a Riemann surface much larger than the \( \mathbb{CP}^2 \), the chiral two-form on \( W \) reduces to a chiral scalar on \( \Sigma \), and the factor of \( 1/2 \) in (3.8) reduces to the factor of one-half difference between (2.10) and (2.24) which was essentially the subject of section two.

We must find another interaction in the theory that can cancel the anomaly (3.8). In the first instance, this interaction is simply the classical interaction \( I_0 = \text{const} \cdot \int_Q C \wedge G \wedge G \) of eleven-dimensional supergravity. The normalization of \( I_0 \) can be most usefully described by noting that if \( Q \) is the boundary of a twelve-manifold \( Y \) over which \( G \) extends, and \( x = G/2\pi \), then
\[ I_0 = -\frac{2\pi}{6} \int_Y x \wedge x \wedge x. \] (3.9)

The factor of \(-1/6\), which was important in [1], is related to \( E_8 \) index theory as explained there.

To prove that \( I_0 \) is invariant under \( \delta C = -d\alpha \), one must integrate by parts and use \( dG = 0 \). But in the field of a five-brane, \( dG \) is not zero; it is a delta function supported on the five-brane world-volume \( W \). So instead of being zero, the gauge variation of \( I_0 \) is a multiple of \( \int_W \alpha \wedge G \), and can potentially cancel (3.7). That the cancellation actually occurs is a consequence of the formula \((1/2) + 3(-1/6) = 0\), where the \( 1/2 \) is present in

\[ ^{17}\text{Of course, (2.13) is the violation of gauge invariance for a non-chiral two-form with chiral coupling to} \ C, \text{while we want a chiral two-form. The difference between the two is crucial in discussing subtle global issues such as those considered in this paper, but not for studying local perturbative anomalies.} \]
the $-1/6$ in (3.9), and the 3 reflects the fact that in comparing the eleven-dimensional interaction $I_0 \sim CGG$ to the seven-dimensional interaction $I_1 \sim CG$, one takes one of the three fields in $I_0$ to be in the normal direction to $W$ and two to be tangential; there are three ways to do this.

What we have just analyzed is a piece of perturbative anomaly cancellation for five-branes, namely the term involving $C$ only. One should also consider perturbative gravitational anomalies for five-branes. Some such terms were studied in [3,7]; a more complete discussion is in section five below. Because of invariance under sign change of $C$ together with reversal of orientation of the normal bundle, there are no “mixed” $C$-gravitational perturbative anomalies.

**Definition Of The Line Bundle**

We now have the crucial clue for how to find the desired line bundle $\mathcal{L} \rightarrow J_W$ and therefore the desired partition function. In the previous examples (chiral boson and chiral two-form on a “bare” six-manifold), the key was to find a Chern-Simons interaction (in a higher dimension) that is gauge-invariant on a closed manifold but not in the presence of a boundary. We now do exactly the same thing, but the higher dimension will be eleven (and not seven, as the previous experience might suggest), and the word “boundary” must be replaced by “five-brane.”

Thus, in $M$-theory, there is a Chern-Simons interaction, schematically $I_M = CGG + CI_8(R)$, where the $CGG$ term is the interaction $I_0$ considered above, and $I_8(R)$ is a certain quartic polynomial in the Riemann tensor [2,3]. The expression

$$W = \det D_{R.S.} e^{iI_M},$$

with $\det D_{R.S.}$ the Rarita-Schwinger path integral, is well-defined [4] on a closed eleven-manifold $Q$. The two factors are not separately well-defined, but as explained in [4], one can alternatively factor (3.10) as follows:

$$W = \left\{ \det D_{R.S.} e^{iI_{R.S.}/2} \right\} \cdot e^{iI_{E_8}}.$$  

(3.11)

Here $I_{R.S.}$ is a properly normalized Chern-Simons term related to the Rarita-Schwinger operator, and $I_{E_8}$ is a properly normalized Chern-Simons term related to $E_8$ index theory. The virtue of the factorization in (3.11) is that the $C$-dependence has been put entirely

---

18 The bordism statement used here is of course Stong’s theorem [19] that $\Omega_1^{spin}(K(\mathbb{Z}, 4)) = 0$. 

25
in $J = e^{iI_{Es}}$, which is a conventional Chern-Simons term, so our general framework will apply. The factor in curly brackets in (3.11) will play practically no role in the discussion.

On an eleven-manifold $Q$ that has a boundary $R$, $J$ is not gauge-invariant in the usual sense, but rather must be interpreted as a section of a line bundle, which we will now call $\mathcal{L}^{-1}$, over the space of fields on $R$. This line bundle $\mathcal{L}^{-1}$ can be described somewhat more concretely by arguments given in section two. Those arguments, after all, had a purely formal character: given any Chern-Simons interaction – such as $I_{Es}$ – which is well-defined on a closed manifold but not on a manifold with boundary, one always produces a line bundle over a suitable space of fields on the boundary. Once $\mathcal{L}^{-1}$ is found, the chiral two-form partition function must be a section of the inverse line bundle $\mathcal{L}$ (to cancel global as well as local anomalies), and therefore its partition function is determined.

Let us now go over some of that ground in a little more fully. Five-branes may sound different from boundaries, but for the present purposes, the two are quite similar. If $W$ is a five-brane world-volume in a space-time $Q$, then the $G$ field has a singularity along $W$. Since singularities are awkward at best and the low energy field theory description is really not valid near the singularity, one might want to cut out of space-time a small tubular neighborhood of $W$. The boundary of that neighborhood is a ten-manifold $R$ which is an $S^4$ bundle over $W$. The fact that $W$ was a five-brane world-volume is now captured by saying that is $S$ is a fiber of $R \to W$, then

$$\int_R \frac{G}{2\pi} = 1.$$  (3.12)

A sensible definition of the chiral two-form partition function should depend only on the local geometry near $W$ – which means, apart from a knowledge of $W$ itself, only a knowledge of the normal bundle to $W$ in $Q$ and a choice of spin structure on a neighborhood of $W$ in $Q$. All this information can be summarized by giving the ten-manifold $R$, together with the map $R \to W$ obeying (3.12), and a spin structure on $R$. (As the normal bundle to $R$ in $Q$ is a trivial real line bundle, the spin structure on $Q$ induces one on $R$.) To obtain a definition of the chiral two-form partition function that only depends on the geometry near $Q$, we should show that we can make the definition given only $R$.

The first step is to define a line bundle $\mathcal{L}^{-1}$ over the space of $C$-fields on $R$, with an action of the local and global gauge transformations. For this we need a well-defined Chern-Simons action on a closed eleven-manifold; we choose for this the object $I_{Es}$. With this Chern-Simons action, the construction in section two now produces a line bundle $\mathcal{L}^{-1}$
over the space of $C$-fields on $R$. We recall that this is done as follows: given a loop $L$ in the space of $C$ fields on $R$, one builds a $C_L$ field on $R \times S^1$, and declares the holonomy of $L^{-1}$ around $L$ to be the value of $e^{iI_{Es}}$ on $R \times S^1$ with $C = C_L$, the antiperiodic spin structure on $S^1$, and the product metric on $R \times S^1$.

To finish, then, all we need is a map $i$ from $C$-fields on $W$ to $C$-fields on $R$ that obey \( (3.12) \) (commuting with local and global gauge transformations). Given such a map, we use $i$ to “pull back” the line bundle $L^{-1}$ from the space of $C$-fields on $R$ to the space of $C$-fields on $W$, and this gives finally the gauge-invariant line bundle we need on the space of $C$-fields on $W$.

The desired $i$ is found as follows. Let $\pi: R \to W$ be the projection, and let $\tau: R \to R$ be the map that commutes with $\pi$ and acts as $-1$ on each $S^4$ fiber of $\pi$. A solution $C_0$ of \( (3.12) \) can be described uniquely up to gauge transformation by saying that $G_0 = dC_0$ is harmonic (remember that $C_0$ can have Dirac string singularities, so that this is possible) and that the field is odd under $\tau$\(^{20}\). The desired map from $C$-fields on $W$ to $C$-fields on $R$ is $C \to \pi^*C + C_0$.

Via $i$, we pull back $L^{-1}$ to the space of $C$-fields on $W$. Restricting to $C$-fields with $G = 0$ and dividing by local and global gauge transformations, we get a line bundle $L^{-1}$ over $J_W$. The chiral two-form partition function is determined by the fact that it is a section of the dual line bundle $L$.

4. Chiral Four-Form In Ten Dimensions

Now we move on to the other somewhat similar example: a chiral four-form $\gamma$ in ten dimensions, which appears in Type IIB superstring theory.

\(^{19}\) An important detail must be checked here. The factorization in \( (3.11) \), by which we eliminated the determinant and reduced to Chern-Simons theory, is unique only up to $I_{Es} \to I_{Es} + I'$, where $I'$ is a properly normalized Chern-Simons interaction constructed from the metric only. To really have a unique construction of $L^{-1}$, the holonomy around the loop $L$ should be independent of the choice of factorization. This is true since $R \times S^1$ with product metric is the boundary of $R \times D$ with product metric ($D$ being a two-disc), and the relevant curvature polynomials are all zero pointwise on $R \times D$ with product metric.

\(^{20}\) For existence of such a field, take any solution $C_0$ of \( (3.12) \) with harmonic $G_0$, and replace it by $(C_0 - \tau^*C_0)/2$. For uniqueness, note that if $C_0$ and $C'_0$ both obey the conditions, then $C' = C_0 - C'_0$ is a closed three-form odd under $\tau$ and therefore (since $\tau$ acts as $+1$ on $H^3(R, \mathbb{Z})$, which is isomorphic to $H^3(W, \mathbb{Z})$) vanishes up to gauge transformation.
The field strength of $\gamma$ is a self-dual five-form $L$. It does not obey $dL = 0$, as one might have guessed. Rather, if $B^i$, $i = 1, 2$ are the two two-forms of Type IIB supergravity (which of course transform in the two-dimensional representation of $SO(2, \mathbb{Z})$), and $H^i = dB^i$, then the relation is

$$dL = \epsilon_{ij} H^i \wedge H^j.$$ (4.1)

This means that if we set $E = \epsilon_{ij} B^i \wedge H^j$, then $E$ behaves as a sort of “composite five-form gauge field” that is coupled to $\gamma$, just as a $U(1)$ gauge field can be coupled to a chiral scalar in two dimensions, and the $C$-field of eleven-dimensional supergravity is coupled to the chiral two-form on a five-brane world-volume.

¿From section two, we know that the partition function of the chiral four-form $\gamma$ on a ten-dimensional spin manifold $W$ will be a section of a line bundle $\mathcal{L}$ over the intermediate Jacobian $J_W$, and that finding the partition function is equivalent to finding a line bundle $\mathcal{L}$ whose first Chern class equals the polarization $\omega$ of $J_W$. We also know that we can always use Chern-Simons theory to find a line bundle of first Chern class $2\omega$, and that we can use Chern-Simons theory to find a line bundle of first Chern class $\omega$ provided that, for a closed twelve-dimensional spin manifold $X$, the intersection form on $H^6(X, \mathbb{Z})$ is always even. This last statement is, happily, true (unlike its counterpart in eight dimensions, whose falsehood made the last section more complicated).

More generally, in fact, the intersection form on the middle dimensional cohomology of a closed spin manifold is always even in $8k + 4$ dimensions. A proof of this using the Adem relations for the Steenrod algebra has been described by J. Morgan.\footnote{The argument is as follows. In $8k + 4$ dimensions, one has a relation in the Steenrod algebra $Sq^{4k+2} = Sq^2 Sq^{4k} + Sq^4 Sq^{4k} Sq^1$. Let $x$ be an element of $H^{4k+2}(X, \mathbb{Z}_2)$, with $X$ an $8k + 4$ dimensional spin manifold. Then modulo two, one has $x^2 = Sq^{4k+2}(x) = Sq^2 (Sq^{4k} x) + Sq^4 (Sq^{4k} Sq^1 x)$. The right hand side vanishes, since $Sq^2$ and $Sq^1$, as maps to the top dimension, are multiplication by $w_2$ and $w_1$, which vanish for a spin manifold.}

One point that should be made about the chiral four-form in ten dimensions is that in using Chern-Simons theory to define the line bundles, the bordism group that one meets is $\Omega_{11}^{spin}(K(\mathbb{Z}, 6))$. (This is the bordism group of an eleven-manifold endowed with a six-dimensional class; it enters in the same way that $\Omega_3^{spin}(K(\mathbb{Z}, 2)) = \Omega_3^{spin}(\mathbb{C}P^\infty)$ entered in section two.) As far as I know, this group has not been computed, and might conceivably be non-zero. If so, then as described at the end of section two, a sort of exotic “theta angle” would appear in the theory, parametrized by the dual group $H =$
Hom(Ω_{11}^{spin}(K(\mathbb{Z}, 6)), U(1)). Such an extra parameter in Type IIB superstring theory seems unlikely, so one might conjecture that in fact Ω_{11}^{spin}(K(\mathbb{Z}, 6)) = 0.

An Example

It may be helpful to present a concrete example, to show that if we are given a specific ten-manifold W (or similarly a specific six-manifold and normal bundle in the five-brane case) we actually can use these considerations to find the line bundle L and therefore the partition function of the chiral field.

The example I will consider is \( W = S^5 \times S^5 \). Call the two factors \( S^5_1 \) and \( S^5_2 \). The middle-dimensional cohomology is \( H^5(W, \mathbb{Z}) = \mathbb{Z} \oplus \mathbb{Z} \), with the two \( \mathbb{Z} \)'s coming cohomology of the two \( S^5 \)'s. The intermediate Jacobian is \( J_W = R^2/(\mathbb{Z} \oplus \mathbb{Z}) \). Let \( a \) and \( b \) be the lattice points \((1, 0)\) and \((0, 1)\) in \( \mathbb{Z} \oplus \mathbb{Z} \). There are two distinguished straight lines \( C_a \) and \( C_b \) in \( J_W \), induced by the straight lines from the origin to \( a \) or \( b \). I claim that the line bundle \( L \) made from the Chern-Simons construction has holonomy 1 around \( C_a \) or \( C_b \). According to (2.17), this determines the holonomy around all cycles and uniquely determines the line bundle \( L \). (For instance, the holonomy on a straight line from the origin to \((1, 1)\) is \(-1\).)

The Chern-Simons construction involves the coupling of the chiral four-form to a background five-form \( E \). (In Type IIB superstring theory, \( E \) is a composite field, found in the discussion of (4.1), but for the present purposes \( E \) might as well be elementary.) For instance, to compute the holonomy around \( C_b \), we must consider the eleven-manifold \( M = S^5_1 \times S^5_2 \times S^1 \), with an \( E \)-field which is the pullback of an \( E \)-field on \( S^5_2 \times S^1 \), and such that if \( K = dE \) is the field strength, then \( \int_{S^5_1 \times S^1} K = 1 \). (\( E \) may also be taken to vary linearly in the \( S^1 \) direction, but we will not need this.) Now, we can regard \( S^5_1 \) as the boundary of a ball \( B^6 \), over which the spin structure extends. So \( M \) is the boundary of \( X = B \times S^5_2 \times S^1 \). The \( E \)-field on \( X \) can be a pullback of an \( E \)-field on \( S^5_2 \times S^1 \). The holonomy around \( C_b \) is to be computed from \( \int_X K \wedge K \). But this vanishes, since \( E \) being a pullback from the last two factors, \( K \wedge K \) actually vanishes point-wise.

So the chiral four-form partition function on \( S^5 \times S^5 \) is determined. As a mathematical corollary, note that it follows that, since \( S^5 \times S^5 \) has only one spin structure, which is therefore preserved by all orientation-preserving diffeomorphisms, the diffeomorphism group of \( S^5 \times S^5 \) does not induce the full \( SL(2, \mathbb{Z}) \) action on \( H^5(S^5 \times S^5, \mathbb{Z}) \), but at most the subgroup preserving the particular line bundle \( L \). (This subgroup can be shown to be of index three.) By contrast, in the superficially similar case of \( S^1 \times S^1 \), the diffeomorphism group does induce the full \( SL(2, \mathbb{Z}) \) action on \( H^1(S^1 \times S^1, \mathbb{Z}) \).
5. Perturbative Anomaly Cancellation For Five-Branes

In this section, we re-examine perturbative anomaly cancellation for $M$-theory five-branes. We have already verified anomaly cancellation for the $C$-field gauge invariance in section three. It remains to consider gravitational anomalies. It turns out that this leads to a surprisingly long story – nothing about five-branes seems to be straightforward! – and we will get a complete answer only for Type IIA, not for $M$-theory.

The five-brane world-volume is a six-manifold $W$ in an eleven-manifold $Q$. $W$ is oriented, and (though this requirement can be relaxed, as $M$-theory conserves parity) we will consider only the case that $Q$ is oriented. Let $TQ$ be the tangent bundle to $Q$ and $TQ|_W$ its restriction to $W$. We have $TQ|_W = TW \oplus N$, where $TW$ is the tangent bundle to $W$ and $N$ is the normal bundle to $W$ in $Q$. $N$, in particular, is an $SO(5)$ bundle over $W$.

Note that a Riemannian metric on $Q$ induces a Riemannian metric on $W$, and a metric and $SO(5)$ connection on $N$. The theory along $W$ therefore has some features of gravity coupled to $SO(5)$ gauge theory.

In analyzing anomalies, it is enough to consider only diffeomorphisms of $Q$ that map $W$ to $W$, since the presence of the five-brane wrapped over $W$ explicitly breaks other diffeomorphisms. A diffeomorphism of $Q$ that maps $W$ to $W$ induces first of all a diffeomorphism of $W$ and secondly an $SO(5)$ gauge transformation of the normal bundle. In fact, diffeomorphisms of $W$ and $SO(5)$ gauge transformations are all that the the world-volume fields (and anomalous interactions) “see” (at least in the long wavelength limit that suffices for computing anomalies) so the discussion will amount to an analysis of gravitational and $SO(5)$ gauge anomalies on $W$.

Perturbative anomalies in $2n$ dimensions are always related to characteristic classes in $2n + 2$ dimensions, so in the present case – as $W$ is six-dimensional – the anomalies will involve eight-dimensional characteristic classes. It turns out to be rather helpful to write the anomalies in terms of Pontryagin classes $p_i(TW)$ and $p_i(N)$. The anomaly eight-form is then a priori a linear combination of $p_2(TW)$, $p_1(TW)^2$, $p_1(N)p_1(TW)$, $p_1(N)^2$, and $p_2(N)$. The terms involving $p_i(TW)$ only have been analyzed before [3,7]; we will extend the analysis to include the other terms. As we will see, the discussion is surprisingly un-straightforward. The known and expected contributions to the $p_1(N)p_1(TW)$ and $p_1(N)^2$ anomalies will cancel, but something new is involved in the cancellation of the $p_2(N)$ term.
There are three known sources of anomalies: (1) world-volume fermions; (2) the chiral two-form; (3) the Chern-Simons couplings of the bulk theory, whose gauge invariance fails in the presence of the five-brane. Their contributions can be determined as follows.

**World-Volume Fermions**

The world-volume fermions are (four-component) chiral spinors on $W$ with values in the (rank four) bundle $S(N)$ constructed from $N$ by using the spinor representation of $SO(5)$. According to standard anomaly formulas [20], the contribution of these fields to the anomaly is

$$I_D = \frac{1}{2} \text{ch}(S(N)) \cdot \hat{A}(TW),$$

(5.1)

where the $1/2$ arises because of considering chiral spinors, ch is the Chern character, and up through dimension eight

$$\hat{A}(TW) = 1 - \frac{p_1(TW)}{24} + \frac{7p_1(TW)^2 - 4p_2(TW)}{5760}.$$  

(5.2)

To compute ch$S(N)$, we note that if the Chern roots of the $SO(5)$ bundle $N$ are $\pm \lambda_1$, $\pm \lambda_2$, and 0, then the Chern roots of $S(N)$ are $\pm (\lambda_1 \pm \lambda_2)/2$. So up through terms quartic in the $\lambda$’s,

$$\text{ch}(S(N)) = \sum_{\epsilon_1, \epsilon_2 = \pm 1} \exp \left[ \frac{1}{2} (\epsilon_1 \lambda_1 + \epsilon_2 \lambda_2) \right]$$

$$= 4 + \frac{1}{2} (\lambda_1^2 + \lambda_2^2) + \frac{1}{96} (\lambda_1^4 + \lambda_2^4 + 6 \lambda_1^2 \lambda_2^2)$$

$$= 4 + \frac{p_1(N)}{2} + \frac{p_1(N)^2}{96} + \frac{p_2(N)}{24}.$$  

(5.3)

In the last step we used $p_1(N) = \lambda_1^2 + \lambda_2^2$, $p_2(N) = \lambda_1^2 \lambda_2^2$. The detailed form of $I_D$ can be obtained by combining the last three equations.

**The Chiral Two-Form**

The chiral two-form propagates on $W$ and does not “see” the normal bundle. The standard anomaly of such a field is

$$I_A = \frac{1}{5760} (16p_1(TW)^2 - 112p_2(TW)).$$  

(5.4)

**Anomaly Inflow From The Bulk**

The third term to consider is the anomaly inflow from the bulk. The eleven-dimensional bulk theory has an interaction proportional to $\tilde{I} = C \wedge (p_1(TQ)^2/4 - p_2(TQ)),$
where $p_1(TQ)$ and $p_2(TQ)$ can be understood as certain polynomials in the Riemann tensor of $Q$. It is important that what appears in $\tilde{I}$ is the Riemann tensor (and therefore the Pontryagin classes) of $Q$, not those of $W$; after all, $\tilde{I}$ is an interaction defined in the eleven-dimensional bulk theory. The relevance to perturbative anomalies of $\tilde{I}$ is that, although gauge-invariant in bulk, it is not gauge-invariant in the field of a five-brane. The anomaly $I_B$ coming from this term is

$$I_B = -\frac{1}{48} \left( \frac{p_1(TQ|_W)^2}{4} - p_2(TQ|_W) \right).$$

(5.5)

As $TQ|_W = TW \oplus N$, we have $p_1(TQ|_W) = p_1(TW) + p_1(N)$, $p_2(TQ|_W) = p_2(TW) + p_2(N) + p_1(N)p_1(TW)$. (5.5) can thereby be rewritten

$$I_B = -\frac{1}{48} \left( \frac{p_1(TW)^2 + p_1(N)^2 - 2p_1(TW)p_1(N)}{4} - p_2(TW) - p_2(N) \right).$$

(5.6)

Upon summing up (5.1), (5.4), and (5.6), one finds that all terms involving $p_i(TW)$ cancel (both the purely gravitational term and the “mixed” term $p_1(TW)p_1(N)$), as does the $p_1(N)^2$ term. The remaining anomaly is in fact

$$\delta = \frac{p_2(N)}{24}.$$  

(5.7)

So something new is needed. It turns out that it is easier to understand the new ingredient if one considers the problem in Type IIA superstring theory rather than in $M$-theory. In other words, we take $Q$ to be $M \times S^1$, where $M$ is a ten-manifold, and we consider the case that the five-brane world-volume $W$ is a submanifold of $M$ (times a point in $S^1$). $M$-theory then becomes equivalent to Type IIA superstring theory, and the five-brane becomes the solitonic five-brane of Type IIA, which couples magnetically to the string theory two-form $B$ (of field strength $H = dB$).

The normal bundle $N$ then becomes $N = N' \oplus O$ where $O$ is a trivial one-dimensional bundle (representing the tangent bundle to $S^1$) and $N'$ (the tangent bundle to $W$ in $M$) is an $SO(4)$ bundle. In particular, $p_i(N) = p_i(N')$ for $i = 1, 2$.

One thing that is special about $SO(4)$, however, is that for an $SO(4)$ bundle – such as $N' - p_2$ can be written in terms of a four-dimensional class, called the Euler class of the bundle, $\chi(N')$. This has its roots in the fact that at the Lie algebra level, $SO(4) = SU(2) \times SU(2)$, so that an $SO(4)$ bundle has two four-dimensional characteristic classes – $p_1$ and $\chi$ – related to the instanton numbers in the two $SU(2)$’s. These are the independent
characteristic classes of an \( SO(4) \) bundle (in general a Lie group of rank \( r \) has \( r \) independent such characteristic classes). So in particular \( p_2 \) can be written in terms of these. The relation is in fact \( p_2(N') = \chi(N')^2 \). \( p_2 \) can be derived from the function \( \lambda_1^2 \lambda_2^2 \) of the Chern roots and \( \chi \) can be derived from the function \( \lambda_1 \lambda_2 \). An expression \( p_2 = \chi^2 \) can exist in \( SO(4) \) but not in \( SO(5) \) because the function \( \lambda_1 \lambda_2 \) is Weyl-invariant in \( SO(4) \) – whose Weyl group acts on the \( \lambda_i \) with pairwise sign changes – but not in \( SO(5) \), whose Weyl group generates independent sign changes of the \( \lambda_i \).

Some notation concerning the Euler class will be helpful. We represent an object \( \alpha \) transforming in the adjoint representation of \( SO(4) \) by a \( 4 \times 4 \) antisymmetric tensor \( \alpha^{ij} \), \( i, j = 1, \ldots, 4 \). In particular, the curvature \( F \) of an \( SO(4) \) connection \( A \) is a two-form \( F^{ij} \) with values in that representation. The Euler class is represented by the four-form \( \chi(F) = \epsilon_{ijkl} F^{ij} \wedge F^{kl} / 32\pi^2 \), where \( \epsilon_{ijkl} \) is the fourth rank invariant antisymmetric tensor of \( SO(4) \). Locally, given a choice of gauge, \( \chi(F) \) is the exterior derivative of a Chern-Simons three-form that we call \( \Omega_\chi(A) \): \( \chi(F) = d\Omega_\chi(A) \). If \( \alpha \) is an \( SO(4) \) gauge generator, we write \( \chi(\alpha, F) = \epsilon_{ijkl} \alpha^{ij} F^{kl} / 16\pi^2 \). The gauge variation \( \delta_\alpha \Omega_\chi \) of \( \Omega_\chi \) under a gauge transformation by \( \alpha \) is
\[
\delta_\alpha \Omega_\chi(A) = d (\chi(\alpha, F)).
\] (5.8)

This equation is part of the “descent” formalism familiar in the study of anomalies.

The Euler Class

The anomaly of interest is thus – in the Type IIA context – \( \chi(N')^2 / 24 \), and it will be necessary to have some understanding of the particular meaning of the characteristic class \( \chi(N') \).

The basic question we have to focus on is: what is the \( H \)-field (that is, the three-form field strength of Type IIA) produced by a five-brane world-volume \( W \) in a ten-manifold \( M \)? The following considerations only involve the behavior near \( W \), and so only depend on the topology of the normal bundle \( N' \) to \( W \) in \( M \). We can in fact replace \( M \) with the total space of \( N' \).

The \( H \)-field is supposed to be a three-form such that \( dH = \delta_W \), where \( \delta_W \) is a delta function supported on \( W \). Such an \( H \) is not uniquely determined, as one could add any smooth, closed \( H \)-field. However, there is an obstruction to existence of \( H \): the obstruction is that \( \chi(N') \) must vanish. This is explained in [21], beginning on p. 70.

The essence of the problem is to precisely formulate what \( \delta_W \) is supposed to be. \( \delta_W \) should be a four-form on \( M \) which is closed, is supported in a small neighborhood of \( W \)
in $M$, and (if one identifies $M$ with the total space of $N'$) integrates to 1 over any fiber of $N' \to W$.

If $B$ is a differential form on a manifold $M$, the restriction of $B$ to a submanifold $W$, written $B|_W$, is obtained by considering only the values on $W$ of components of $B$ tangent to $W$. Thus $B|_W$ is a differential form on $W$ (of the same degree as $B$). The theory of the Thom isomorphism and the Euler class, as described in \cite{21}, shows that any $\delta_W$ with the properties stated in the last paragraph has the further property that $\delta_W|_W$ is in the cohomology class of $\chi(N')$, the Euler class of the normal bundle $N'$. If a connection $A$ on $N'$ is picked, so that $\chi(N')$ is represented by a differential form $\chi(F)$ (as defined above), then one can in a very natural way pick $\delta_W$ such that

$$\delta_W|_W = \chi(F). \quad (5.9)$$

Now it is clear why there is a restriction on the possible topology of the normal bundle to a five-brane. The “magnetic” field of the five-brane is supposed to be a three-form $H$ obeying

$$dH = \delta_W, \quad (5.10)$$

but this implies

$$d(H|_W) = \delta_W|_W = \chi(F). \quad (5.11)$$

Such an $H$ can exist only if the differential form $\chi(F)$ is trivial cohomologically, that is only if the characteristic class $\chi(N')$ vanishes.

A form with the properties of $\delta_W$ could be constructed using any connection $A$ on $N'$, but when $W$ is embedded in $M$ as a five-brane world-volume, there is a distinguished connection – coming from the Riemannian connection of $M$ – and therefore a distinguished four-form $\chi(F)$ representing the Euler class of the normal bundle. (5.10) is part of the naive idea of what a five-brane wrapped on $W$ is supposed to be, but is not usually stated precisely enough to exhibit the “finite part” of the delta function along $W$ that appears in (5.11). We will assume in the rest of this paper that (5.11) should be taken as part of the definition of a five-brane.

Since the anomaly we are trying to eliminate is proportional to $\chi(N')^2$, the vanishing of $\chi(N')$ means that the integrated anomaly vanishes in a suitable sense. That is not enough; we need to cancel the anomaly locally, since gauge transformations are local. But vanishing of the integrated anomaly at least means that there is no topological obstruction
to finding a counterterm that would cancel the anomaly. In fact it is easy to see, using (5.11), that there is such a counterterm. It is

$$\tilde{L} = \int_W H|_W \wedge \Omega_x(A),$$

where again $A$ is the Riemannian connection on $N'$ and $\Omega_x$ was introduced above. Indeed, using (5.8) and (5.11) and integrating by parts, the variation of $\Delta L$ under gauge transformations of $N'$ is

$$\delta_\alpha \tilde{L} = -\int_W \chi(F) \wedge \chi(\alpha, F),$$

and this is the six-form related by the usual “descent” procedure to the anomaly eight-form $\chi(F)^2/2$.

So a multiple of $\tilde{L}$ will cancel the $\chi(N')^2$ perturbative anomaly. Moreover, given the invariance of Type IIA superstrings under reversal of orientation of $N'$ together with sign change of $H$, this is the only anomaly that can be canceled by such a term. It is thus gratifying that precisely this term is the one whose contributions from previously known interactions do not cancel.

**Back To M-Theory**

For $M$-theory five-branes, we need a generalization of this, but how to do so is somewhat puzzling. The replacement of $SO(4)$ by $SO(5)$ and of $\chi(N')^2$ by $p_2(N)$ makes even the absence of a topological obstruction to canceling the anomaly mysterious. For a specific five-brane world-volume $W$, $p_2(N)$ vanishes, as $W$ is six-dimensional. But the topological interpretation of anomalies involves considering certain two-parameter families of physical objects [22], and one could perfectly well have a two-parameter family of $W$’s with non-zero $p_2(N)$ over the total space. It is not clear what sort of physical mechanism would suppress such families in $M$-theory.

Beyond canceling the topological obstruction, we need to actually find a local counterterm that cancels the $p_2(N)$ anomaly. The fact that this counterterm must reduce to (5.13) under the appropriate conditions makes it clear roughly what the desired counterterm must be, though the matter still seems rather obscure. For an $SO(5)$ bundle $N$, the closest analog of the characteristic class $\chi$ is a certain four-form with values in $N$, defined by

$$\chi_e = \frac{F^{ab} \wedge F^{cd} \epsilon_{abcde}}{32\pi^2}.$$
The factorization $p_2 = \chi^2$ that holds for $SO(4)$ bundles becomes for $SO(5)$ bundles

$$p_2(N) = \sum_e \chi_e \wedge \chi_e.$$  \hfill (5.15)

In $M$-theory, the fundamental differential form in space-time is not a three-form $H$ but a four-form $G$. However, along $W$, one can define an $N$-valued three-form, namely the part of $G$ with three indices tangent to $W$ and one $N$-valued index. Let us write this part of $G$ as $H_e$, where $e$ is the $N$-valued index, and the indices tangent to $W$ are not written explicitly. The analog of (5.12) must be something like

$$\int_W \sum_e H_e \wedge \Omega_e$$  \hfill (5.16)

where $\Omega_e$ is an $N$-valued three-form related to $\chi_e$. $H_e$ must also obey an $N$-valued version of (5.11). It is not clear exactly what the right equations are. The fact that the story works so nicely for Type IIA nevertheless gives some faith that a satisfactory answer must exist in $M$-theory.
