We measured and compared the electric field vs current density characteristics in the vortex state of two amorphous Nb0.7Ge0.3 microbridges, with and without a line of submicron holes patterned along the sample axis. The power dissipation in the perforated sample exhibits a crossover, being reduced at temperatures well below the superconducting transition temperature $T_c$ and unexpectedly enhanced close to $T_c$. At low temperatures the holes are efficient artificial pinning centres and reduce the average vortex velocity. We argue that the dissipation enhancement close to $T_c$ is a consequence of a combination of the weakened pinning by the holes and an inhomogeneous driving-current distribution in their vicinity, which results in an increased average vortex velocity as well as in a channeling of the vortex motion through the holes.

The rapid development of nanostructuring methods in the last decade has enabled highly precise fabrication of artificial pinning centres (APCs) for vortices in superconductors. It has already been proved that point-like inclusions in a superconducting film, such as perforating conductors. It has already been proved that point-like artificial pinning centres (APCs) for vortices in superconductors. It has already been proved that point-like artificial pinning centres (APCs) for vortices in superconductors. It has already been proved that point-like artificial pinning centres (APCs) for vortices in superconductors.

Vortex dynamics in the presence of a line of submicron holes along a superconducting microbridge

The simplest APC is a small perforating hole in a superconductor, having magnetic permeability larger than its diamagnetic surroundings. The most efficient pinning is obtained if the hole diameter is comparable to the magnetic-field penetration depth $\lambda$ rather than the coherence length $\xi$, as one may expect at first sight. This was predicted by virtue of the Ginzburg-Landau (GL) theory for a single hole and observed experimentally for arrays of holes. The relevance of $\lambda$ for the artificial pinning potential is a consequence of the comparatively small supercurrent kinetic energy required for preserving the flux-quantisation condition around a hole not smaller than $\lambda$.

Local interactions of vortices with holes in the presence of a driving current have not yet been studied in detail experimentally. These go beyond the cited matching phenomena and are important for understanding the function of holes in an arbitrary arrangement, which may have implications for possible design of future devices based on the manipulation of artificially pinned vortices. In this report we present such an investigation facilitated by arranging the holes in a line centred along the main axis of a superconducting microbridge [lower inset to Fig. 1(a)], which eliminates the matching phenomena but still provides a sufficient signal arising from the presence of the holes. In addition, we have minimised the influence of the intrinsic pinning by using the amorphous superconductor Nb0.7Ge0.3, which is known for its very low background pinning.

The vortex motion was detected by recording the electric field vs current density characteristics $E(J)$ in three different temperature regimes, over a wide range of applied currents, and $B$ up to the upper critical magnetic field $B_{c2}$. Close to $T_c$ we observed a clear increase of the power dissipation by the holes over the whole range of $B$ and $J$. This result can be explained plausibly by taking into account a local enhancement of the vortex driving force due to a spatial modulation of the driving-current density around the holes. To our knowledge such current-modulation effects have so far been disregarded in the interpretation of previous experiments carried out on perforated superconductors. Well below $T_c$ the holes pin the vortices and reduce the dissipation, which shows that their usefulness as APCs may extend to low temperatures if the intrinsic pinning is weak. Our results imply that the interplay of hole pinning and inhomogeneous current drive determines whether the holes enhance or reduce the dissipation in the vortex transport.

Two $210 \mu m$ long, $5 \mu m$ wide and $20 nm$ thick microbridges between two large contact pads were sput-
FIG. 1: $E(J)$ of sample N (○) and sample P (•) for (a) $T = 1.1$ K, $B = 0.9$ T, (b) $T = 2.0$ K, $B = 0.6$ T and (c) $T = 2.5$ K, $B = 0.25$ T. The solid and dashed lines are plots of LO $\rho_f$ expected at low and high $t$, respectively. Lower inset to (a): A sketch of sample P (not to scale) and the designation of the directions (see the text). Upper inset to (a) and insets to (b), (c): The initial parts of the $E(J)$ in an expanded scale for a better view.

tered onto the same Si/SiO$_2$ substrate as described in Ref.[11]. Both samples had the same $T_c = 2.75$ K and the same overall normal-state and superconducting properties. Throughout the paper we use the nonperforated sample (sample N) as a reference for identifying the effects of holes. Its transport properties were analysed in detail in Ref.[11] and its GL parameters $\xi(0) = 6.8$ nm and $\lambda(0) = 1.15$ $\mu$m are taken as representative of both samples. The perforated sample (sample P) contained a line of equidistant holes along the central axis of the microbridge (designated as $x$ direction) as sketched in the lower inset to Fig. 1(a). The holes had a diameter of 800 nm [slightly smaller than $\lambda(0)$] and their centre-to-centre distance was 1.2 $\mu$m. A magnetic field was applied perpendicularly to the film plane and a dc current was passed in the $x$ direction, so that the vortices traversed the sample in the $y$ direction. The current sweep rate was 10 nA s$^{-1}$. The applied current is for sample P converted into the average current density $J_P$ by calculating the (uniform) current density $J_N$ for sample N and taking the ratio of the normal-state resistances to determine $J_P = 1.23 J_N$. We use this notation, together with $E_N$, $E_P$ for the electric field in samples N and P, respectively, when referring to the $E(J)$ of the two samples specifically. At high $J$ the $E(J)$ exhibit nonlinearities due to the flux-flow instabilities that are related to the nonequilibrium changes of vortex cores. Here we concentrate on the close-to-equilibrium regime where these effects have not yet been developed and the vortex cores maintain their equilibrium properties.

In Fig. 1 we plot typical $E(J)$ representative of three temperature regimes: (a) $T$ well below $T_c$ (1.1 K, $t = 0.4$), (b) intermediate $t$ (2.0 K, $t = 0.7$), (c) $T$ close to $T_c$ (2.5 K, $t = 0.91$). The open circles show $E_N(J_N)$, solid circles $E_P(J_P)$, and the lines different theoretical predictions of the Larkin-Ovchinnikov (LO) flux flow (FF) theory as discussed below. The scaled magnetic field $b = B/B_{c2}$ corresponds to 0.30 - 0.38, the $B_{c2}$ values being (a) 3.0 T, (b) 2.0 T and (c) 0.65 T, with the uncertainty of around 5%. At low $T$ [Fig. 1(a)] the $E(J)$ of both samples reveal two different dynamic regimes: thermally activated magnetoresistance at $J \to 0$, followed at larger $J$ by an $E \propto (J - J_c)$ behaviour that implies FF against a background pinning potential with a depinning threshold $J_c$. As can be seen, the power dissipation in sample P is lower for $\sim$ 10% throughout the whole current-density range, suggesting an efficient pinning by the holes even far below $T_c$. In Fig. 1(b) we show the $E(J)$ at $T = 2.0$ K ($t = 0.7$), just at the boundary of the low- and high-$t$ regimes, displaying a weaker reduction of $E_P$ below $E_N$. Close to $T_c$ [Fig. 1(c)] the theoretical high-$t$ LO $\rho_f$ (see Ref.[11] for details), shown by the dashed line, describes $E_N(J_N)$ excellently starting from $J = 0$ and up to the appearance of the nonlinearities mentioned before. However, over the entire current-density range the dissipation in sample P is larger than in sample N, unexpectedly and in contrast to the result at lower temperatures. The reason for this peculiar behaviour cannot be found in the pinning properties of holes.

The magnetic field range over which $E_N \neq E_P$ is wide at all three characteristic temperatures. This is demonstrated in Fig. 2, where we plot the ratio $p = P_P/P_N$ of the power density dissipated in samples P and N vs
The situation is opposite. We have checked whether the dissipation is not affected by the FF instabilities. Each curve performed over the maximum region where the holes reduce the dissipation ($p < 1$) whereas close to $T_c$ the situation is opposite.

$b = B/B_{c2}$. The integration $P_{N,P} = \int E_{N,P} dJ_{N,P}$ is for each curve performed over the maximum region where the dissipation is not affected by the FF instabilities. We have checked whether $p$ depends on the upper limit of integration, and we found minor numerical differences of the order of 10 - 15 % of the values shown in Fig. 2, with no change in the general shape of $p(b)$. As can be anticipated from the $E(J)$ shown in Figs. 1(a),1(b), for $t = 0.4$ and $t = 0.7$ we find $p < 1$, i.e. the holes are active pinning sites and decrease the dissipation. Their relative contribution to the pinning becomes smaller as $t$ and $b$ increase, which is expected qualitatively and discussed later. Close to $T_c$ the dissipation in sample P is always larger, thus $p > 1$ with a maximum around $b \approx 0.4$. This enhancement implies a suppression of the artificial pinning by another effect which is fully manifested close to $T_c$.

In order to understand the above results one has to address the equation of motion for the vortices

$$m \ddot{u} = F_d - \eta u + F_h,$$

where $u$ is the vortex velocity, $\eta$ the vortex-motion viscosity, $m$ the effective vortex mass per unit length, $F_d = \phi_0 J \times \dot{z}$ the driving force ($\dot{z}$ is the unit vector in the direction of the applied magnetic field), and $F_h$ being the repulsive force between the mobile vortices and those pinned by the holes. The spatial dependence of the $i$-th component of the vortex acceleration $\ddot{u}$ is given by $\ddot{u}_i = u \cdot \nabla u_i$. For our qualitative reasoning we have neglected other contributions (e.g. the interaction of mobile vortices with each other or with intrinsic pinning potential). Knowing the supercurrent distribution $J(r)$ one can solve Eq. (1) to find the vortex-velocity profile $u(r)$. The generated electric field, the $x$ component of which contributes to measured $E_P$, is calculated as $E(r) = u(r) \times B(r)$, where $B(r)$ is related to the local vortex density $n(r) = B(r)/\phi_0$. When confining a pinned vortex each hole acts as a source of repulsion to other vortices, with $F_h$ pointing radially from the centre of the hole. The repulsive force between two vortices separated by $r \ll \lambda$ is given by $\lambda^{-2} \ln(\lambda/r)$ and therefore weakens as $\lambda \to \infty$. Furthermore, the probability of a vortex being pinned by a hole becomes progressively smaller as $\lambda$ grows much larger than the hole diameter. Hence it is reasonable to assume that $F_h$ decreases monotonically with increasing $\lambda$ and eventually becomes irrelevant in the limit of diverging $\lambda$ at $T \to T_c$. In the following we discuss the results for $t = 0.91$ assuming $F_h = 0$.

We note that the driving force $F_d$ is not uniform around the holes because the supercurrent density $J$ is spatially modulated. A schematic of the modulation of $J$, and consequently of $F_d$, around the holes is shown in Figs. 3(a) and 3(b) by the dashed lines. In the regions denoted by H the driving force is larger than far from the holes, while in the regions denoted by L the situation is the reverse. With $F_h \approx 0$ in the vicinity of $T_c$, the vortices are accelerated parallel to $F_d$ (perpendicular to $J$), thus the vortex trajectories accumulate in regions H as sketched in Fig. 3(a) by the solid lines. The second effect of the current modulation is that in regions H the vortices move faster than in the sample bulk and produce a larger...

![FIG. 2: The ratio $p = P_d/P_N$ of the power dissipated in samples $P$ and $N$, integrated up to the appearance of the flux flow instabilities, vs $b = B/B_{c2}$. Sufficiently below $T_c$ the holes reduce the dissipation ($p < 1$) whereas close to $T_c$ the situation is opposite.](image)

![FIG. 3: A qualitative consideration of the vortex trajectories (arrowed solid lines) around the holes at (a) $T$ close to $T_c$ and (b) $T$ well below $T_c$. The modulated current is indicated by the arrowed dashed lines, the density of which represents the magnitude of $J$. Arrowed dotted lines in (b) depict the repulsion exerted by the vortices pinned by the holes to other vortices. The labels L and H denote regions of low and high vortex flow density, respectively.](image)
local electric field, while in regions L the opposite happens. Although the holes themselves shorten the distance the fast vortices travel in regions H, a sufficient imbalance in favour of the number of these vortices, together with their large acceleration, may result in the total dissipation in sample P being larger than in sample N. Therefore if a highly dense two-dimensional array of holes is intended to be used for enhancing the pinning of a sample there is no guarantee that this will work close to $T_c$ in the presence of a transport current, although the magnetisation loops may widen up. Moreover, the current-induced vortex-velocity enhancement strengthens with increasing $J$, which also occurred at a relatively large applied current.

The nonmonotonic $b$ dependence of $p > 1$ may be linked to the competition between the enhanced current drive around the holes and the mutual repulsion of the mobile vortices, as explained below. The excess electric field relative to that far from the holes is estimated as $\Delta E \sim \phi_0 \Delta u \Delta n$, where $\Delta u$ and $\Delta n$ are the effective excess vortex velocity and density in regions H, respectively. While $\Delta u$ depends on $J$, $\eta$, $m$, and is independent of $B$, $\Delta n$ also depends on the repulsive interaction between the mobile vortices, which is weak at low $b$ and strong at high $b$. At low fraction $b = B/B_c$ of the volume filled with the vortices they can all easily be channeled through regions H. Thus a larger vortex density results in the larger $\Delta n$ and $\Delta E$. On the other hand, $\Delta n$ is at high $b$ limited by the reduced space available for the channeling, which decreases $\Delta E$ and in turn results in a nonmonotonic $p(b)$.

As temperature is lowered $\lambda$ becomes smaller and the holes start to pin more efficiently, which explains qualitatively the stronger reduction of the dissipation at lower temperatures (Fig. 2). The vortices trapped by the holes now repel the incoming vortices and change the vortex trajectories depicted in Fig. 3(a) to those shown in Fig. 3(b). The repulsive force $F_R$ is indicated by the dotted arrows. In a simple model of pinning by the holes in dynamic conditions, a vortex remains pinned by a hole for some time until it is replaced by an incoming vortex. At low vortex density almost all vortices in the vicinity of holes are either pinned by them or scattered to pass through the regions L of low current density. Hence, the holes cause a noticeable reduction of the dissipation. As $B$ increases the incoming vortices exert more force upon those pinned at the holes, reduce the pinning time, and the overall suppression of the dissipation decreases. This qualitative picture may explain the behaviour of $p(b)$ at low temperatures.

In conclusion, we have patterned a line of holes with a diameter close to $\lambda(0)$ along an amorphous Nb$_{0.7}$Ge$_{0.3}$ microbridge. A comparison of the measured $E(J)$ curves of the samples with and without perforation reveals an unusual crossover in the power dissipation close to and well below $T_c$. Close to $T_c$ the artificial pinning is weak and an unexpected rise of the dissipation is observed. This is attributed to the inhomogeneous current distribution around the holes leading to a significant increase of the local vortex velocity. As temperature is lowered the pinning by the holes becomes stronger and eventually suppresses the vortex velocity enhancement. In addition, our weak background pinning has permitted, to our knowledge, the first observation the pinning properties of holes as artificial pinning centres far below $T_c$.
