Abstract

NEXT (Neutrino Experiment with a Xenon TPC) is a neutrinoless double-beta ($\beta\beta_0\nu$) decay experiment that will operate at the Canfranc Underground Laboratory (LSC). It is an electroluminescent high-pressure gaseous xenon Time Projection Chamber (TPC) with separate read-out planes for calorimetry and tracking. Energy resolution and background suppression are the two key features of any neutrinoless double beta decay experiment. NEXT has both good energy resolution ($< 1\%$ FWHM) at the Q value of $^{136}\text{Xe}$ and an extra handle for background identification provided by track reconstruction. With the background model of NEXT, based on the detector simulation and the evaluation of the detector radiopurity, we can determine the sensitivity to a measurement of the $\beta\beta_2\nu$ mode in NEW and to a $\beta\beta_0\nu$ search in NEXT100. In this way we can predict the background rate of $5 \times 10^{-4}$ counts/(keV kg yr), and a sensitivity to the Majorana neutrino mass down to 100 meV after a 5-years run of NEXT100.

Keywords: time projection chamber, radioactivity, background, double beta decay, NEXT

1. Neutrinoless double beta decay

Neutrinoless double beta decay ($\beta\beta_0\nu$) is a postulated nuclear transition in which two neutrons undergo $\beta$ decay simultaneously without the emission of neutrinos.

Evidence of this process would establish that massive neutrinos are Majorana particles, provide a hint of a new physics scale beyond the Standard Model and prove the violation of total lepton number, a key element to explain the observed asymmetry between matter and antimatter in the universe. In addition, the measurement of the $\beta\beta_0\nu$-decay rate would provide information on the absolute scale of neutrino masses \textsuperscript{[1]}, as shown in Eq.\textsuperscript{1}:

$$\frac{T_{1/2}^{0\nu}}{T_{1/2}^{2\nu}} \propto m_{\beta\beta}^{2}$$ \textsuperscript{(1)}

2. Double beta decay experiments

Double beta decay detectors measure the sum of the kinetic energies from the two released electrons, $Q_{\beta\beta}$. Considering the finite energy resolution ($\Delta E$) of any detector, other processes occurring in the detector, as the tail of the $\beta\beta_2\nu$ mode, can fall in the region of energies around $Q_{ reli}$ becoming background. As in other rare event detectors, backgrounds of cosmogenic origin and natural radioactivity from materials are a problem, and thus underground operation and selection of radiopure materials is essential. In this sense additional experimental features are desired to improve the sensitivity of the detector, such as extra background (B) rejection, better detector efficiency ($\epsilon$) or larger exposure ($M \cdot t$) \textsuperscript{[1]}. This relation can be summarized as follows:

$$T_{1/2} \propto a \cdot \epsilon \cdot \sqrt{\frac{M \cdot t}{\Delta E \cdot B}}$$ \textsuperscript{(2)}

3. NEXT-100

The NEXT-100 detector will search for the neutrinoless double beta decay of $^{136}\text{Xe}$ at the Laboratorio Subterráneo de Canfranc. It uses a time projection chamber filled with 100 kg of enriched xenon gas at 15 bar pressure, with separated detection functions for calorimetry and tracking \textsuperscript{[2]}. The gaseous xenon provides scintillation and ionization as primary signals. These are used to establish the start-of-event time ($t_0$) and for calorimetry/tracking respectively. In order to achieve optimal energy resolution, the ionization signal is amplified in NEXT using the electroluminescence (EL) of xenon \textsuperscript{[3]}.

\textbf{Calorimetry}: The energy plane is made of 60 photomultiplier tubes (Hamamatsu R11410-10 PMTs), lo-

4. Background model

A detailed simulation of the detector performance has been implemented in NEXUS, the Geant4-based simulation program of the NEXT experiment. This let us evaluate all the main backgrounds that can mask the $\beta\beta_2\nu$ signal, coming from the activities of the materials to be used in the construction (Table 1). The NEXT Collaboration is carrying out a thorough campaign of material screening and selection with the assistance of the LSC Radiopurity Service [5].

Figure 1 shows the expected background and $\beta\beta_2\nu$ signal in the NEW prototype. With the operation and first results of NEW the accuracy of this model will be validated and improved if needed. Using this model the background rate expected in NEXT-100 is estimated to be as good as $5 \times 10^{-4}$ counts/(keV kg yr) [6].

5. Analysis and Sensitivity

The output of the simulation are hits of energy deposited in the active volume of the detector. A standard analysis of those simulated events produced by the modeling has been developed. This analysis has been implemented in the same way as will be done for the real data based on the features that NEXT offers taking into account the detection and reconstruction effects. Here is a brief description of the selection algorithms applied to the events made by the analysis:

- A first raw cut on event’s energy is made to reduce the amount of data produced by the simulation. Only those events with energy greater than 0.6 MeV are written in the preprocessing.
- $\beta\beta$ events are produced in the active volume, while background events come from the materials enclosing it. Therefore, only those events that are fully contained in an inner fiducial volume, far enough from the walls, are selected.
- Detection and reconstruction effects are taken into account by smearing the event true energy according to the expected resolution of the detector.
Table 2: Acceptance of the selection cuts for signal ($\beta\beta_0\nu$) and backgrounds.

| Selection cut | $\beta\beta_0\nu$ | $\beta\beta_2\nu$ | $^{214}\text{Bi}$ | $^{208}\text{Tl}$ |
|---------------|------------------|------------------|-----------------|-----------------|
| $E \leq (2.3, 2.6)$ MeV | $0.276$ | $3.1 \times 10^{-6}$ | $1.52 \times 10^{-6}$ | $8.02 \times 10^{-7}$ |
| Fiducial | $0.678$ | $2.95 \times 10^{-6}$ | $1.13 \times 10^{-6}$ | $4.77 \times 10^{-7}$ |
| Single track | $0.508$ | $2.27 \times 10^{-6}$ | $1.36 \times 10^{-6}$ | $4.84 \times 10^{-7}$ |
| $dE/dx$ | $0.381$ | $1.70 \times 10^{-6}$ | $1.36 \times 10^{-6}$ | $8.10 \times 10^{-7}$ |
| ROI | $0.319$ | $3.24 \times 10^{-12}$ | $1.2 \times 10^{-7}$ | $3.2 \times 10^{-7}$ |

- A more precise cut on the energy of the events is made selecting only those that enter in our region of interest (ROI) window. That window is defined before in order to maximize the sensitivity and change among the $2\nu$ or the $0\nu$ analysis.

- One of the features of NEXT is the ability to reconstruct event topology. The simulated events are reconstructed with the voxelization algorithm (looks for a finite space volume with an energy deposition different from zero) to $1 \text{ cm}^3$ 3D hits. Afterward those hits are interconnected forming the track produced by the particle in the detector. Those tracks are analyzed comparing their associated end blob (high energy deposition in a small region). The event tracks with one blob (background-like) are discarded and those with two blobs (signal-like) at the ends are selected. In Figure 2 is clearly shown the different fingerprint made by background and signal like events, that allow us to use this criteria to enhance our sensitivity.

Figure 2: Energy of one blob vs energy of the other blob for signal ($0\nu$) and background (Bi214) events.

With the aforementioned rejection factors (Table 2) and the background model, the half-life sensitivity of NEXT-100 is estimated to be $1.1 \times 10^{26}$ years, corresponding to an effective neutrino mass of $\sim 100 \text{ meV}$, after 5 years running (500 kg y of exposure) [6].

Figure 3: NEXT-100 simulated $\beta\beta_0\nu$ signal corresponding to a mass of 100 meV and backgrounds entering into the region of interest.
