Ostwald ripening in Two Dimensions: Correlations and Scaling Beyond Mean Field.

Boris Levitan and Eytan Domany

Department of Physics of Complex Systems, Weizmann Institute of Science, Rehovot, Israel
(August 26, 2021)

We present a systematic quasi-mean field model of the Ostwald ripening process in two dimensions. Our approach yields a set of dynamic equations for the temporal evolution of the minority phase droplets’ radii. The equations contain only pairwise interactions between the droplets; these interactions are evaluated in a mean-field type manner. We proceed to solve numerically the dynamical equations for systems of tens of thousands of interacting droplets. The numerical results are compared with the experimental data obtained by Krichevsky and Stavans for the relatively large volume fraction \( \varphi = 0.13 \). We found good agreement with experiment even for various correlation functions.

I. INTRODUCTION

When a system is quenched into a two-phase coexistence region, its homogeneous initial state no longer corresponds to thermodynamic equilibrium. If there is a conserved quantity whose density is different in the two coexisting phases (such as the total volume or total amount of impurities), the final equilibrium state consists of two macroscopic domains, separated by a single phase boundary. The manner in which a system evolves from its homogeneous initial state to the final equilibrium state of two-phase coexistence has been the subject of numerous theoretical and experimental investigations.

For small initial super-saturation the system’s evolution towards two-phase equilibrium starts by nucleation and growth of droplets (or small crystallites) of the minority phase. In the late stage of evolution to the equilibrium state no new droplets are formed and the amount of material in each of the phases remains fixed. Evolution proceeds by means of dissolution of small droplets and growth of the large ones, giving rise to reduction of the total (surface) energy of the system. The exchange of material is driven by diffusion; the concentration is higher near surfaces with high curvature, and hence the diffusive flux is directed from the small droplets towards the larger ones. This coarsening process, called Ostwald ripening, in the course of which the number of droplets decreases, while the average size of the remaining ones increases, is the subject of the present paper.

In what follows we describe a formalism that leads to an efficient numerical algorithm for Ostwald ripening in two dimensions. Our work was motivated by, and our results are compared with recent experimental work on a two-dimensional film of liquid and crystalline succinonitrile in coexistence. Therefore we will refer to the minority phase as ”solid”, and to the matrix in which the droplets are embedded as ”liquid”.

Ostwald ripening belongs to a family of non-equilibrium phenomena that exhibit evolution to a scaling state. By a scaling state we mean that there is a single length scale in the system, which grows with time. For Ostwald ripening the obvious length scale is the average droplet size \( \langle R \rangle \); its growth with time follows the celebrated Lifshitz-Slyozov law, \( \langle R \rangle \sim t^{1/3} \). When rescaled by this changing length, all statistical characteristics of the system (such as droplet size distribution, spatial correlations etc) are time-independent. That is, by comparing two photographs of the system, taken at different (well separated) times but properly rescaled, one cannot tell from any statistical measurement which photograph was taken earlier.

A parameter of central importance on which various characteristics of the system (such as the droplet size distribution) depend is the relative volume fraction of the minority phase, \( \varphi \). This parameter determines the ratio of the size of the droplets and the distance between them. Therefore, \( \varphi \) controls the extent to which droplets interact with each other; for very small volume fractions the interaction is weak, and any particular droplet ”feels” the effect of the others only through an effective medium. This observation served as the basis of the theoretical, mean-field model (see ref. for a review). As \( \varphi \) increases correlations between neighboring droplets become more important, until mean field based approximations lose their validity. The effects of correlations have been taken into account analytically to first order in a small parameter. In three dimensions the small parameter is \( \varphi / \sqrt{\varphi} \) (see Marder, and in two - \( 1/ \log \varphi \) (see Zheng and Gunton). The obtained expressions are so complicated even in first order, that it is hard to see how one can proceed to higher orders. Rather, a combined analytical and numerical approach seems to be suitable.

The basic phenomenological description of Ostwald ripening is provided in the framework of a Cahn-Hilliard equation (see ref. for a review) for the order parameter. Rogers and Desai performed such a “first princi-
ple computation, reaching the scaling state with about 500 droplets. This was achieved for small values of \( \varphi \) (less than 0.1), when all the droplets were almost circular. Such a number of droplets suffices for studying the droplet size distribution, but is too small to gain insight into the spatial and temporal correlations in the scaling state. Moreover, for larger fractions the final stage of the coarsening process was not achieved in the calculation and scaling was not observed. Masbaum used this method recently for a simulation, performed on a parallel computer, starting with about 3000 droplets. He obtained rather good agreement for various correlation functions with the experiments of Krichevsky and Stavans.

It is clear, however, that this method can hardly be applied for studying much larger systems, which are needed in order to make statistically meaningful measurements in the late-stage scaling regime. Therefore one turns to simplified descriptions of the system, hoping that the main features of the full Cahn-Hilliard theory are preserved. For the sake of completeness, we briefly present below a sequence of approximations that lead from the full Cahn-Hilliard theory to our approach.

First, one goes to a coarse-grained representation of the order parameter field, which retains the boundaries between the crystalline droplets and the surrounding liquid as one of the dynamic variables of the problem. The second variable is the diffusing concentration field (of the impurities or the liquid itself), \( c(\vec{r}) \). Simplification of the problem is attained by separation of time scales. The process which occurs on fastest scales is the equilibration of the concentration near the (moving) boundaries. Assuming that this occurs instantaneously allows us to write the Gibbs-Thomson condition for the concentration at a point on the boundary of a droplet, where the (local) radius of curvature is \( R(t) \);

\[
c|_{\text{droplet}}(t) = c_{eq}(R(t)) = c_{\infty} + \frac{\alpha}{R(t)},
\]

Here \( c_{\infty} \) is the equilibrium concentration in a liquid above a planar liquid-solid interface. The problem becomes now one of solving the diffusion equation

\[
\frac{\partial c}{\partial t} = \nabla^2 c \tag{2}
\]

with boundary conditions given by Eq.(1) on moving boundaries.

The rate of change of the boundaries is determined by \( J_\perp = \vec{n} \cdot \vec{J} \), the mass flux normal to the droplet’s surface, which, in turn, is proportional to the gradient of the concentration field at the boundary;

\[
\frac{dR}{dt} = -J_\perp \quad \vec{J} = -\nabla c|_R. \tag{3}
\]

Equations Eq.(1-3) constitute a closed dynamical problem. The next simplification is a quasi-static approximation to the problem. For fixed boundary conditions the diffusing field would reach a steady state in a characteristic diffusion time \( t_D \sim R^2 \), where \( R \) is a typical length scale (distance between neighboring droplets). If this time is much shorter than the growth time \( t_G \), i.e. the time it takes a typical droplet’s radius to change appreciably, the concentration field reaches a steady state before the radii of the droplets had a chance to change and one can use the stationary diffusion equation instead of Eq.(3). This is precisely the case for late stages of the growth process, where \( t_G \sim R^3 \), so that indeed \( t_D \ll t_G \). The Lifshitz-Slyozov scaling law, \( t \sim R^3 \), can be established by dimensional analysis of Eqs.(1) and (3). Hence at late stages the solution \( c(\vec{r}, t) \) of Eq.(2) can be approximated by the solution of the stationary diffusion problem

\[
\nabla^2 c = 0 \tag{4}
\]

with the previous boundary conditions Eq.(1); but now we look for a solution of Eq.(4), from which the rate of change of the boundaries is obtained using Eq.(3), giving rise to new boundaries at the next time step, and so on. It should be noted that in this approximation the total area of the droplets is conserved exactly.

It is possible to reformulate the stationary diffusion problem Eqs.(1) - (4) as an integral equation which automatically accounts for the boundary conditions. Expanding the shapes of the droplets using a set of orthogonal polynomials one can reduce the problem to an implicit system of ordinary differential equations in terms of the expansion coefficients. Further simplification can be achieved by neglecting the deviation of the droplet shapes from circular. We expect this approximation to work for low volume fractions \( \varphi \), when the distances between the droplets are much larger than the droplets sizes and redistribution of material in a single droplet is much faster than the exchange between the well separated droplets. However, experiments show that even for fractions as large as \( \varphi = 0.4 \) the droplets are more or less circular. Therefore, we consider Laplace's equation Eq.(4) with the boundary conditions Eq.(1) at perfectly
circular domains of radii $R_i$, positioned at points $r_i$. This is a problem in electrostatics - of calculating the potential in the presence of conducting cylinders. One approximates the solution of this problem by

$$c(r) = \sum_i q_i \log(|r - r_i|/R_0) + \sum_i \frac{(\vec{p}_i \cdot (\vec{r} - \vec{r}_i))}{|\vec{r} - \vec{r}_i|^2},$$

where $R_0$ is an arbitrary length. The "charges" $q_i$ and the "dipoles" $p_i$ should be chosen so that the boundary conditions (1) are satisfied (approximately) on the surface of each droplet. Let us denote by $X_{ij} = |r_i - r_j|$ the distance between the centers of droplets $i$ and $j$, and by $c/r_i$ the correct boundary value of the concentration, as given by Eq.(1). We now approximate the concentration field at the boundaries by its expansion to first order in the small parameter $R_i/X_{ij}$:

$$c_\infty + \frac{\alpha}{R_i} = c(\vec{r}_i + \vec{R}_i) \approx q_i \log R_i/R_0 + \frac{(\vec{p}_i \cdot \vec{R}_i)}{R_i^2} +$$

$$+ \sum_{j \neq i} q_j \log(X_{ij}/R_0) + \sum_{j \neq i} \frac{(\vec{p}_j \cdot \vec{X}_{ij})}{|X_{ij}|^2} + \sum_{j \neq i} q_j \frac{(\vec{X}_{ij} \cdot \vec{R}_i)}{|X_{ij}|^2}.$$  

(6)

$\vec{R}_i$ denotes the radius-vector of points on the surface of droplet $i$; the last term appears as the expansion of $q_j \log |\vec{r}_i + \vec{R}_i - \vec{r}_j|$. Equation (6) contains two parts; one that depends on the direction of $\vec{R}_i$ and one that does not. This results in two sets of linear equations for the charges and the dipoles:

$$c_\infty + \frac{\alpha}{R_i} = q_i \log R_i/R_0 + \sum_{j \neq i} q_j \log(X_{ij}/R_0) + \sum_{j \neq i} \frac{(\vec{p}_j \cdot \vec{X}_{ij})}{|X_{ij}|^2},$$

(7)

$$\frac{(\vec{p}_i \cdot \vec{R}_i)}{R_i^2} + \sum_{j \neq i} q_j \frac{(\vec{X}_{ij} \cdot \vec{R}_i)}{|X_{ij}|^2} = 0.$$  

(8)

As we will see, the last term in Eq.(7) is $O((R/X)^2)$ - i.e. smaller than the other terms and can be omitted. Thus the system of equations

$$c_\infty + \frac{\alpha}{R_i} = q_i \log R_i/R_0 + \sum_{j \neq i} q_j \log(X_{ij}/R_0)$$

determines the charges. Since Eq.(8) should be satisfied for any $\vec{R}_i$, the dipoles are determined by

$$\frac{\vec{p}_i}{R_i^2} = - \sum_{j \neq i} \frac{\vec{X}_{ij} \cdot \vec{R}_i}{|X_{ij}|^2}.$$  

(10)

The physical meaning of the Eq.(10) is that the dipole associated with droplet $i$ is simply related to the electric field induced at its center by all the other charges. Once the charges are obtained from solving Eq. (10), their substitution in Eq.(10) determines the dipoles.

The normal component of the flux at the boundary of droplet $i$ is given by

$$\vec{\nabla}_n c(\vec{r}_i + \vec{R}_i) = \frac{q_i}{R_i} - 2 \frac{(\vec{p}_i \cdot \vec{R}_i)}{R_i^3},$$

(11)

where Eq. (8) and (10) were used. The normal flux has two contributions; an isotropic part, giving rise to a rate of change of the radius, given by

$$\frac{dR_i}{dt} = \frac{q_i}{R_i}$$

and an anisotropic part, due to the dipole term in Eq.(11). The contribution of the dipole part to the total flux vanishes; it induces deposition of material on one side of the droplet and evaporation from the opposite side. We
approximate the effect of the dipole flux by shifting the positions of the circular droplets (see below). We also show (in Appendix A) that in the low concentration ($\varphi << 1$) limit the effect of the dipoles is negligible; we first discuss this limit, working with charges only, and then include the dipoles.

Eq. (12) implies that the rate of change of the area of droplet $i$ is proportional to its charge $q_i$. Using $q_i$ from Eq. (12) in Eq. (11) eliminates the concentration field $c(\vec{r})$ from the problem and, after proper rescaling of variables, the following set of equations for the temporal evolution of the radii results:

$$ (1 + R_i/R_c) = \sum_j L_{i,j} \dot{R}_j, \quad (13) $$

where $R_c = \alpha/\varepsilon_\infty$ is a capillary length and the matrix $L_{i,j}$ defined in 2-d as follows:

$$ L_{i,j} = \begin{cases} \log(R_i/R_0) & \text{if } i = j \\ \log(X_{i,j}/R_0) & \text{otherwise.} \end{cases} \quad (14) $$

Clearly, solving the system Eq. (13)-(14) is a much simpler computational task than solving the Laplace problem Eq. (11) with moving boundary conditions on the surfaces of the droplets. Note, however, that the matrix elements $L_{i,j}$ grow with the distance between the droplets. Because of this, finite size effects become crucial: all droplets in the bulk feel the boundary. The simplest way to avoid this problem is to consider the system with periodic boundary conditions; the interaction of a pair of droplets contains an infinite sum of logarithms, corresponding to all the images of these droplets. Yao et al.\cite{Yao} have summed this series using Ewald summation techniques.

The problem is further complicated by the need to invert the $N \times N$ matrix $L_{i,j}$ at each time step in order to get from Eq. (13) explicit expressions for $\dot{R}_i$. Thus, solving the system (13-14) takes $N^3$ operations per time step; therefore each run costs $N^4$ operations. This necessitates huge CPU times (the simulations of Yao et al.\cite{Yao} took about 1000 CPU hours on an IBM 3090 computer for a system of about 3000 droplets).

Beenakker\cite{Beenakker} has solved an analogous problem in 3-d by truncating the matrix $L_{i,j}$ (defined in 3-d in a way analogous to Eq. (14)). He took into account only the interactions between droplets whose separation does not exceed a threshold, reducing this way the number of droplets with which a given one interacts to about 20. The physical motivation for such truncation is screening\cite{Helfrich,Beenakker}; droplets whose separation exceeds the screening length do not affect each other. It should be noted that with such a truncation the total volume of the droplets is not conserved, and Beenakker had to adjust $R_c$ in Eq. (14) at each time step in order to restore volume conservation.

Akaiwa and Meiron\cite{Akaiwa} used the analogous truncation procedure in 2-d. Although the interactions between the charges are expected to be well screened even in 2-d, formal truncation of the matrix seems problematic in this case. Since the matrix elements grow with distance between the droplets, the elements of the inverse matrix as functions of the cutoff should contain large fast oscillating components (unlike in 3-d, where their dependence on the cutoff is smooth). Nevertheless, their results (in particular, the correlation functions) compare well with experiment. Apparently, this success is due to the fact that these oscillations are effectively averaged out during the run.

Our goal was to find an analytic way of approximating $L^{-1}$, in a manner that reflects screening as the physical basis of the approximation scheme. Once $L$ has been inverted, we can integrate the equations

$$ \dot{R}_i = \sum_j L_{i,j}^{-1} (1 + R_j/R_c), \quad (15) $$

numerically. The approximation introduced in this work can be summarized by the expression

$$ \dot{R}_i = \sum_j L_{i,j}^{-1} = \frac{1}{R_i K_0(R_i/\zeta_{sc})} \sum_{j\neq i} K_0(X_{i,j}/\zeta_{sc}) \left( \frac{1}{R_j} - \frac{1}{R_i} \right), \quad (16) $$

where $K_0$ is the zeroth order modified Bessel function of the second kind (also called MacDonald function). Since $K_0(x) \sim \exp(-x)$ for large $x$, the parameter $\zeta_{sc}$ has the meaning of a screening length. In the mean field limit (i.e. for very small area fraction $\varphi$) it is determined by the equation:

$$ \zeta_{sc}^{-2} = 2\pi R \left( \frac{1}{K_0(R/\zeta_{sc})} \right). \quad (17) $$

However, for larger fractions, where the effects of correlations become important, $\zeta_{sc}$ is determined by a more complicated condition, as discussed in Appendix B. In practice, in our simulations for $\varphi = 0.13$ we used $\zeta_{sc} = 2.73 R$, as determined by Table I (see Appendix B for details).
As explained in Appendix A, Eq.(20) can be replaced by a heuristic formula, simpler than that of Eq.(20), which leads to the following dynamical equation for the droplet’s radius:

$$R \frac{dR}{dt} = k(R/\zeta) \left( \frac{1}{R} - \frac{1}{R_c} \right),$$

(18)

where $k(x) = xK_1(x) / K_0(x)$, while $\zeta$ is defined by the equation: $\zeta^{-2} = 2\pi n \langle k(R/\zeta) \rangle$. Since $xK_1(x) \to 1$ for $x \to 0$, we find $k(x) \to 1/K_0(0)$ and our definition of the screening length coincides with his.

We used the formalism presented above to integrate the evolution of large assemblies of droplets and found that at relatively large values of the area fraction $\varphi$ the droplets’ motion, induced by the so far neglected dipoles becomes important and must be taken into account.

We evaluate now the contribution of the dipoles to the shift of the droplets’ centers of mass, $\delta \tilde{r}_i$, defined by

$$M \delta \tilde{r} = \int \tilde{R} \delta m.$$  

Here the integration is over the boundary of a droplet; $\tilde{R}$ is a radius vector on its boundary, $M = \rho \pi R^2$ is the total mass of the droplet ($\rho$ is the density; it will drop out of the final result) and $\delta m$ is the additional mass adsorbed (or lost) locally, due to the shift of the boundary during the interval $dt$. The anisotropic component of the local velocity of the droplet’s boundary is given by

$$v = -J_n = -\frac{2\rho \cos \theta}{R^2},$$

where $\theta$ is the polar angle between $\tilde{R}$ and $\tilde{p}$. The mass added at $\tilde{R}$ is

$$\delta m = \rho(vdt)(Rd\theta) = -\frac{(2\rho/R)d\theta}{R^2} \cos \theta \ d\theta,$$

so that (see also Appendix A of [1])

$$\frac{d\tilde{r}}{dt} = -\frac{2\rho}{\pi R^3} \int \tilde{R} \cos \theta \ d\theta = -\frac{2\tilde{p}}{\pi R^2} \int \cos^2 \theta \ d\theta = -\frac{2\tilde{p}}{R^2}.$$ 

Finally, we find

$$\frac{d\tilde{r}_i}{dt} = -\frac{2\tilde{p}_i}{R_i^2} = 2 \sum_{j \neq i} \frac{q_j}{|X_{i,j}|} \frac{X_{i,j}}{|X_{i,j}|},$$

(20)

Note, that both sides of Eq.(20) have the same dimensionality, since the charges $q_i$ are measured in area per time (see Eq.(12)).

The procedure for solving Eq.(13) - (14) for the dynamics of the droplets’ radii $R_i$, together with Eq.(21) for their positions $\tilde{r}_i$ is as follows. For given $\tilde{r}_i$ and $R_i$ we invert $\tilde{L}$, obtain $dR_i/dt$ (or $q_i$ as given by Eq.(12)) and integrate one time step. Next, substituting $q_i$ into Eq.(20) we obtain new values of $\tilde{r}_i$ and the procedure is repeated.

The sum on the r.h.s. of Eq.(20) appears to be problematic: assuming that the droplets’ charges are uncorrelated (while the total charge is zero) one can see that the mean square of this sum diverges logarithmically with the size of the system. However, as we show in Appendix A, the correlations between the charges, provided by screening, ensure the convergence of this sum, so that it can be evaluated using a reasonable fraction of its terms. Actually, a heuristic formula, simpler than that of Eq.(20), can be used to evaluate the droplets’ shifts in practical simulations. As explained in Appendix A, Eq.(20) can be replaced by

$$\frac{d\tilde{r}_i}{dt} = 2 \sum_{j \neq i} \frac{K_{i,j}}{k_i k_j} \left( \frac{1}{R_i} - \frac{1}{R_j} \right) \frac{X_{i,j}}{|X_{i,j}|^2},$$

(21)

where $K_{i,j} = K_0(X_{i,j}/\varsigma_{sc})$ and $k_i = K_0(R_i/\varsigma_{sc})$. Although the approximation leading to this formula is not clearly established, our simulations show that it works as well as the more rigorous Eq.(20). At the same time it is much
more economic because only droplets that lie within the screening length (from the droplet whose shift is evaluated) contribute to the sum.

In the sequence of approaches to the Ostwald ripening problem in two dimensions, ranging from the Cahn-Hilliard equation to Marqusee’s mean field theory, our model, which includes only the pairwise interaction between the droplets, can be viewed as the minimal extension of the mean field approach. This concerns our Eq.(21) (in comparison with the Eq.(20)) as well. We believe that our approach constitutes the simplest step that can be taken beyond simple mean field.

Our program is as follows. In the next section we present a few universal properties of the matrix $L$. This is followed by Section III, where we derive the main result, Eq.(16), using a mean-field type approximation to $L^{-1}$. Numerical solutions of the resulting dynamics, based on Eq.(16), and on both (20) or (21), are presented in Section IV and compared with experiments by Stavans and Krichevsky. Section V presents a short summary of our approach and results.

II. SOME SUM RULES

We present now some important properties of the matrix $L^{-1}$, that lead to useful “sum rules”. The first claim is that

$$\sum_i L_{i,j}^{-1} R_i = \sum_j L_{i,j}^{-1} R_j \to 0$$

the sum approaching zero as the system size increases. This relationship is analogous to one presented for the 3-d case by Beenakker and Ross. We present here arguments (that seem to us simpler than those of ref. 22) for the validity of Eq.(22) in 2-d. First consider the quantity

$$a_j = \sum_i L_{i,j}/R_j = \sum_i R_i \log(X_{i,j}/R_0).$$

The sum is clearly dominated by regions that are far from $\vec{r}_j$; in the absence of long-range correlations the composition of such regions does not depend on the identity of droplet $j$. On the other hand, the contribution of those droplets $i$ that lie near droplet $j$ will, in general, depend on $R_j$. By “near” we mean the region for which correlations are important. The size of this region is, however, small (on the order of the screening area - see below), the values of $X_{i,j}$ in this region are small, and the contribution from it is negligible compared to those from the far-away parts of the plane. That is, for increasing system size $a_j \to \infty$, whereas the contribution from the correlation region remains finite. Hence we can write

$$a_j = \sum_i L_{i,j}/R_j \simeq a \to \infty.$$  \hspace{1cm} (24)

Next, consider the following sum:

$$1 = \sum_k \delta_{ik} = \sum_k \sum_j L_{i,k}^{-1} L_{j,k} = \sum_j L_{i,j}^{-1} R_j \sum_k L_{j,k}/R_j = \sum_j L_{i,j}^{-1} R_j a_j$$

using now Eq.(24) we get

$$a \sum_j L_{i,j}^{-1} R_j \simeq 1$$

so that

$$\sum_j L_{i,j}^{-1} R_j \simeq a^{-1} \to 0$$

and hence statement Eq.(22) holds in the limit of large system size. An immediate consequence of Eq.(27) is obtained by using it in Eq.(15), yielding

$$\dot{R}_i = \sum_j L_{i,j}^{-1}.$$
Thus we see that the length $R_c$ drops out from the description of the dynamics of the system.

Multiplying by $R_i$ and summing over $i$, and using again Eq. (27), we establish area conservation

$$
\sum_i R_i \dot{R}_i = \sum_j \left( \sum_i L_{ij}^{-1} \dot{R}_i \right) = 0
$$

(29)
as a consequence of our sum rule. Another important consequence is the following observation: $L_{ij}^{-1}$, the elements of the inverse matrix, are independent of the parameter $R_0$. To see this, take the derivative of $(L^{-1}L)_{i,k}$ with respect to $\log R_0$: clearly $(L^{-1})'L + L^{-1}L' = 0$ and hence

$$(L^{-1}_{i,m})' = -\sum_{jk} L^{-1}_{ij} L'_{jk} L^{-1}_{km}.$$  

(30)

But from Eq. (14) we immediately get that $(L_{j,k})' = -R_j R_k$, which when used in Eq. (30) gives

$$(L^{-1}_{i,m})' = -\sum_j \sum_k (L^{-1}_{k,m})' R_k L^{-1}_{i,j} R_j$$

(31)

and when Eq. (27) is used here, we get

$$(L^{-1}_{i,m})' = 0$$

(32)

and hence $L^{-1}_{ij}$ does not depend on $R_0$; and in view of Eq. (28) the system’s dynamics is, therefore, also independent of $R_0$.

III. MEAN FIELD APPROXIMATION TO $L^{-1}$

Let us decompose the matrix $\hat{L}$ of Eq. (14) to its diagonal and off-diagonal parts,

$$\hat{L} = \hat{L}_0 - \hat{L}_1,$$

(33)

where $(\hat{L}_0)_{i,j} = \delta_{i,j} R_i^2 \log(R_i/R_0)$ and $(\hat{L}_1)_{i,j} = -R_i R_j \log(X_{i,j}/R_0)$. Note, that only the off-diagonal part contains interactions between different droplets. One could consider an expansion of $\hat{L}^{-1}$ in powers of the interaction:

$$\hat{L}^{-1} = (1 - \hat{L}_0^{-1} \hat{L}_1) \hat{L}_0^{-1} = \sum_{n=0}^{\infty} (\hat{L}_0^{-1} \hat{L}_1)^n \hat{L}_0^{-1}$$

(34)

with $\hat{L}_0^{-1}$ given by

$$(\hat{L}_0^{-1})_{i,j} = \delta_{i,j} \frac{1}{R_i^2 \log(R_i/R_0)}. $$

(35)

Clearly, for matrix elements that correspond to well separated droplets (i.e. when $X_{ij} \gg R_0$), terms of order $n + 1$ will be larger than those of order $n$: that is, the series diverges formally and in order to obtain meaningful results one should perform some kind of partial summation to all orders. To do this we introduce the $T - matrix$, defined by

$$\hat{L}^{-1} = \hat{L}_0^{-1} + \hat{L}_0^{-1} \hat{T} \hat{L}_0^{-1}.$$ 

(36)

To ensure that $\sum_j L_{i,j} L_{j,k}^{-1} = \delta_{i,k}$, $\hat{T}$ has to satisfy the equation

$$\hat{T} = \hat{L}_1 + \hat{L}_1 \hat{L}_0^{-1} \hat{T}.$$ 

(37)

For the sake of convenience we introduce a new matrix $\hat{\phi}$, defined by

$$T_{i,j} = R_i R_j \hat{\phi}_{i,j}.$$ 

(38)
Once the matrix $\phi_{i,j}$ has been found, it is straightforward to write down $\hat{T}$ and, using Eq. (36), the inverse matrix $\hat{L}^{-1}$. Rewriting Eq. (37) in terms of $\hat{\phi}$ we get

$$\sum_{j \neq i} \frac{1}{\log(R_j/R_0)} \log(X_{i,j}/R_0)\phi_{j,k} + \phi_{i,k} = -(1 - \delta_{ik}) \log(X_{i,k}/R_0).$$

(39)

For the diagonal elements this takes the form

$$\phi_{k,k} = -\sum_{j \neq k} \frac{1}{\log(R_j/R_0)} \log(X_{k,j}/R_0)\phi_{j,k},$$

(40)

whereas for the off-diagonal elements we obtain from Eq. (39)

$$\sum_{j \neq i,k} \frac{1}{\log(R_j/R_0)} \log(X_{i,j}/R_0)\phi_{j,k} + \phi_{i,k} = -\gamma_k \log(X_{i,k}/R_0)$$

(41)

where

$$\gamma_k = 1 + \frac{\phi_{k,k}}{\log(R_k/R_0)}.$$  

(42)

It should be noted that equations (40-42) are exact. In principle for any configuration of droplets, the set of equations (39) are to be solved for the matrix elements $\phi_{i,k}$. We approximate the solution of this problem in a mean-field spirit. The central premise of this mean field approach is that the off-diagonal matrix elements $\phi_{i,j}$ depend only on the distance $X_{i,j}$, i.e.

$$\phi_{i,j} = \phi(|\vec{r}_i - \vec{r}_j|).$$

(43)

That is, we are interested only in the pairwise interaction between the droplets (neglecting any possible dependence of $\phi_{i,j}$ on other droplets). The analogous approximation for the diagonal elements is that they are all equal, i.e. $\phi_{m,f}^{mf}$ is independent of $k$;

$$\phi_{k,k} \approx \phi_{k,k}^{mf} = \phi_0.$$  

(44)

To obtain manageable mean-field equations the following simplifying assumptions are made:

1. In sums such as (40-41) replace $1/\log(R_j/R_0)$ by its average value.
2. Approximate these sums by integrals;
3. Set in Eq. (41) $\gamma_k = \gamma$ for all $k$ (i.e. impose independence of $k$).

We will discuss and justify these steps below, but before doing that, we investigate the resulting approximation to Eq. (41), given by

$$-\frac{1}{2\pi} \zeta_0^{-2} \int \log(X_{i,j}/R_0)\phi(X_{i,k})d^2r_j + \phi(X_{i,k}) = -\gamma \log(X_{i,k}/R_0),$$

(45)

where

$$\zeta_0^{-2} = 2\pi n \left\langle \frac{1}{\log(R_0/R)} \right\rangle \approx 2\pi n \frac{1}{\log(R_0/\langle R \rangle)}$$

(46)

and the angular brackets denote averaging over the distribution of droplet sizes (that is, the average value obtained in the particular droplet configuration in which $\hat{L}^{-1}$ is evaluated).

The integral equation (45) can be solved easily by operating with $\nabla^2$ on the left and the right hand sides. Using the identity $\nabla^2 \log r = 2\pi \delta(\vec{r})$ we obtain the following differential equation for $\phi(x)$:

$$-\zeta_0^{-2} \phi + \nabla^2 \phi = -2\pi \gamma \delta(\vec{r}).$$

(47)

Its solution is the MacDonald function,
\[ \phi_{i,k} = \phi(X_{i,k}) = \gamma K_0(X_{i,k}/\zeta_0) \quad i \neq k \quad (48) \]

\[
K_0(r/\zeta_0) \approx \begin{cases} 
-\log(r/2\zeta_0) - C & r \ll \zeta_0 \\
\sqrt{\frac{2\zeta_0}{\pi}} e^{-r/\zeta_0} & r \gg \zeta_0
\end{cases} \quad (49)
\]

where \( C \approx 0.5772 \) is Euler’s constant.

Let us discuss briefly this result. First of all note that self consistency of the approximation imposes positivity of \( \zeta_0^2 \), i.e. \( R_0 \gg \langle R \rangle \). This is indeed the case, as will be discussed below. Next note that the divergence of \( \phi(r) \) at short distances is an artifact of the approximations we made by replacing the exact discrete equation (41) by the continuous Eq.(40). This divergence has no physical consequences, since the diagonal elements of the matrix \( \hat{L} \) are not given by the solution of Eq.(47); rather, they are determined by Eq.(40).

One should note also that if \( \gamma_k \) were to depend on \( k \) the result (48) would have become \( \phi_{i,k} = \gamma_k K_0(X_{i,k}/\zeta_0) \), implying that \( \phi_{i,k} \neq \phi_{k,i} \), whereas the matrices \( \hat{L} \) and \( \hat{\phi} \) must be symmetric (see Eqs. (36) and (38) and remember that \( \hat{L} \) is symmetric).

The diagonal elements are expressed in terms of the off-diagonal ones in Eq.(40); using there the approximations listed above and the mean-field expression (48) for the off-diagonal elements, Eq.(40) becomes

\[ \phi_{k,k} \approx \frac{1}{2\pi} \zeta_0^{-2} \int \log(X_{k,j}/R_0) K_0(X_{j,k}/\zeta_0) d^2r_j = \phi_0 \quad (50) \]

as anticipated in Eq.(44). Using this in Eq.(42) yields

\[ \gamma_k = 1 + \frac{\phi_0}{\log(R_k/R_0)} \]

and in order to get a consistent mean field approach, with \( \gamma_k \) independent of \( k \) (as required by the assumption No. (3) from our list), we must have \( \phi_0 = 0 \). To set \( \phi_0 = 0 \) we will now use our freedom to adjust the parameter \( R_0 \). As discussed in the Section II, we are free to vary this parameter, since it does not affect the dynamics. Thus we arrive at the following condition on \( R_0 \):

\[ \phi_0 = \frac{1}{2\pi} \zeta_0^{-2} \int \log(X_{k,j}/R_0) K_0(X_{j,k}/\zeta_0) d^2r_j = 0. \quad (51) \]

After some simple but lengthy transformations, given in Appendix C, Eq. (51) becomes the following approximate expression for \( \log R_0 \):

\[ \left\langle \frac{1}{\log(R_0/R)} \right\rangle \approx \left\langle \frac{1}{K_0(R/\zeta_0)} \right\rangle. \quad (52) \]

Substituting Eq.(52) in Eq.(40) yields a closed equation for \( \zeta_0 \), with no dependence on \( R_0 \):

\[ \zeta_0^{-2} = 2\pi n \left\langle \frac{1}{\log(R_0/R)} \right\rangle \approx 2\pi n \left\langle \frac{1}{K_0(R/\zeta_0)} \right\rangle. \quad (53) \]

Note that once we find \( \zeta_0 \), we can use this equation also to determine \( R_0 \). This will not be necessary since \( R_0 \) drops out of the dynamic equations, as shown below. Equation (53) is almost identical to Marqusee’s expression for the screening length. In principle we can now proceed as planned; for any droplet configuration evaluate \( \zeta_0 \), calculate the mean field approximation to the matrix \( \phi \),

\[ \phi_{i,j} \approx K_0(X_{i,j}/\zeta_0) \quad \phi_{k,k} \approx 0 \quad (54) \]

substitute in Eqs.(35) and (34) to get \( \hat{L}^{-1} \) and use it in the dynamic equation (27). There is a problem with doing this, though. An important property of the exact \( \hat{L}^{-1} \) is that it satisfies the sum rule (24) and hence the total area of all droplets is conserved by the dynamics (see Eq. (29)). Since Eq.(54) is an approximation, we have to check the extent to which the sum rules are satisfied by our approximate \( \phi \). Substituting (54) in (36) yields

\[
\hat{L}^{-1}_{i,i} = \frac{1}{R_i^2 \log(R_i/R_0)}, \quad \hat{L}^{-1}_{i,j} = \frac{K_0(X_{i,j}/\zeta_0)}{R_i \log(R_i/R_0) R_j \log(R_j/R_0)}. \quad (55)
\]
Note that \( \hat{L}^{-1}_{i,j} \) are small at distances \( X_{i,j} \gg \zeta_0 \); hence the parameter \( \zeta_0 \) should be interpreted as a screening length. At short distances the solution of Eq. (47) behaves like the lowest order approximation (i.e. stopping at \( n = 1 \) in the expansion (54)). Using these expressions in the sum rule (27) gives

\[
\sum_j L^{-1}_{i,j} R_j \approx \frac{1}{R_i \log(R_i/R_0)} \left[ 1 + \sum_{j \neq i} \frac{1}{\log(R_j/R_0)} K_0(X_{i,j}/\zeta_0) \right]
\]

(56)

When we approximate the sum by an integral, in the spirit of our mean-field approach, it becomes

\[
\sum_{j \neq i} \frac{1}{\log(R_j/R_0)} K_0(X_{i,j}/\zeta_0) \rightarrow -\frac{1}{2\pi \zeta_0^2} \int K_0(r/\zeta_0) d^2 r = -1
\]

and the right hand side of (56) vanishes, so that in the mean-field limit (i.e. for vanishing area fraction; see Appendix D) when our approximations become exact, the sum rule is indeed satisfied. If, however, we use Eq. (55) for practical calculations at a non vanishing area fraction, the sum rule (and hence area conservation) will not be satisfied rigorously.

This problem can be overcome rather simply in the following way. Adopt the mean-field approximation (55) for the off-diagonal elements of \( \hat{L}^{-1} \), and use the sum rule (27) to determine its diagonal elements:

\[
\hat{L}^{-1}_{i,i} = -\frac{1}{R_i} \sum_{j \neq i} L^{-1}_{i,j} R_j
\]

The result for both diagonal and off-diagonal elements of \( \hat{L}^{-1} \) can be summarized as

\[
\hat{L}^{-1} = \begin{cases} 
\frac{1}{R_i \log(R_i/R_0)} \sum_j K_0(X_{i,j}/\zeta_0) & \text{if } i=j \\
R_i R_j \log(R_j/R_0) & \text{otherwise}.
\end{cases}
\]

(57)

With this approximation for \( \hat{L}^{-1} \) the sum-rule is of course exactly satisfied in every step and area is conserved. In the mean-field limit the sum in Eq. (57) yields \(-1\), and the expression for \( \hat{L}^{-1}_{i,i} \) obviously reduces to the naive one, given by Eq. (55).

Using Eq. (57) in Eq. (28) we obtain now a rather elegant expression for \( \hat{R}_i \), the rates of change of the droplets’ radii:

\[
\hat{R}_i = \sum_j L^{-1}_{i,j} = \frac{1}{R_i \log(R_i/R_0)} \sum_{j \neq i} K_0(X_{i,j}/\zeta_0) \left( \frac{1}{R_j} - \frac{1}{R_i} \right).
\]

(58)

For a given droplet configuration we have now an explicit expression for the dynamics of the droplets’ radii (note that the values of the parameters \( R_0 \) and \( \zeta_0 \) are also determined by the configuration). As a final "cosmetic" adjustment, we use Eq. (52) to replace logarithms by \( K_0 \) (thereby eliminating \( R_0 \) from the dynamics), yielding the equation we used in our numerical study:

\[
\hat{R}_i = \frac{1}{R_i K_0(R_i/\zeta_0)} \sum_{j \neq i} K_0(X_{i,j}/\zeta_0) \left( \frac{1}{R_j} - \frac{1}{R_i} \right).
\]

(59)

To complete the treatment we now justify our naive approach, discuss the regime in which our approximation is expected to hold, and check whether various assumptions that were made are self-consistent. First of all we assumed that \( R_0 \) can be chosen so that \( \zeta_0^2 > 0 \). Now we can see from Eq. (52) that the "optimal" \( R_0 \approx \zeta_0 \), and since in the mean-field limit \( \zeta_0 \gg R_0 \) this means that \( R_0 \gg R_i \) for all \( i \), so that by Eq. (13) \( \zeta_0^2 \) is indeed positive and our approach is self-consistent.

The central point of our approach was replacement of the sum Eq. (11) by an integral:

\[
\sum_{j \neq i,k} \frac{1}{\log(R_j/R_0)} \log(X_{i,j}/R_0) \phi_{j,k} \rightarrow n \left( \frac{1}{\log(R_j/R_0)} \right) \int \log(X_{i,j}/R_0) \phi(X_{j,k}) d^2 r_j
\]

(60)

It is intuitively clear that such a substitution is valid as long as \( N_\zeta \), the number of droplets in the screening zone is large. Now, after having obtained the solution \( \phi \), we can indeed show that the condition \( N_\zeta \gg 1 \) holds when \( \log(\phi^{-1}) \gg 2\pi \).
Therefore we have $N\alpha$ near $V$ screening length, will have only a small contribution to $N\phi$ their procedure still did not guarantee precise area fraction conservation: when the number of droplets got reduced $\\epsilon$ time step. Let $17$ this reason, Akaiwa and Meiron needed to ensure that the relative change of $\\langle K \rangle$ will become $18$ as was done by Yao et al. We require our algorithm to conserve area fraction exactly, whose separation from $\alpha$ exceeds considerably the $\phi$-$\beta$ dependence of $N\phi$. We note that a droplet whose separation from $\alpha$ exceeds considerably the $\phi$-$\beta$ dependence of $N\phi$. Say we wish to integrate (61)-(62) naively. For each time step we have to evaluate all $N\phi$ terms, i.e. $N\phi$ operations per time step. If we have initially $N$ droplets, and wish to reach the late stages with a few $\\%$ surviving, we would have to perform $N\phi$ steps $\\sim N$ time steps of integration, as was done by Yao et al. This is so because if the time step is greater than the life time of some droplet, its area will become negative at the end of the time step, which leads to an increase of the area fraction of the surviving droplets. Therefore, apparently in order to guarantee exact area conservation one must eliminate each shrinking droplet separately, restricting the end step by the next vanishing. At the same time, the detailed evolution of the smallest droplet is absolutely unimportant for us. Rather we would like to choose $\tau$ to be not smaller than it is needed to ensure that the relative change of $(R)$, the mean radius of the droplets, is small during one time step. For this reason, Akaiwa and Meiron simply removed the droplets with $R < \epsilon(R)$ with $\epsilon = 0.1$ before performing the time step. Let $f_s$ be the fraction of the droplets that are eliminated in each time step (it is kept constant, to a good approximation, by fixing $\epsilon$). Then the number of steps needed for a run is reduced to $N\phi$ steps $\\sim (1/f_s) \log N$. However, their procedure still did not guarantee precise area fraction conservation: when the number of droplets got reduced by a factor of 5 (from 100 000 to 20 000), the change of $\\phi$ was about $2\\%$. We require our algorithm to conserve area fraction exactly and, nevertheless, to reduce both $N\phi$ and $N\phi$ steps $\\sim (1/f_s) \log N$: that is, our scheme requires $O(N \log N)$ operations for the entire evolution.

To reduce the $N$-dependence of $N\phi$ we note that a droplet $\beta$, whose separation from $\alpha$ exceeds considerably the $\\phi$-$\beta$ dependence of $N\phi$. We achieved $N\phi$ $\sim N$ and $N\phi$ steps $\\sim (1/f_s) \log N$: that is, our scheme requires $O(N \log N)$ operations for the entire evolution. Therefore we have $N\phi$ $\sim N$ (replacing $N^2$).
To reduce $N_{\text{steps}}$ to $N_{\text{steps}} \approx (1/f_s) \log N$, *conserving the area fraction*, we should treat accurately the vanishing of the small droplets, instead of simply removing them before performing the time step, as is done in ref.\(^1\). Putting this into practice requires care, however. Let us consider the system of droplets at two consecutive times $t_0$ and $t_1 = t_0 + \tau$. We call all droplets that survive to $t_1$ "large" and denote them by indices $i$ and $j$, whereas droplets that vanished before $t_1$ are called "small" and marked by indices $n, m$. With this notation Eqs. (61)-(62) become

$$\frac{dS_i}{dt} = \sum_j v_{i,j} + \sum_m v_{i,m},$$

(63)

$$\frac{dS_m}{dt} = \sum_n v_{m,n} + \sum_j v_{m,j}.$$  

(64)

We choose $\tau$ to be small enough so that the density of small droplets is small; hence the typical distance between two small droplets exceeds considerably the screening length. Therefore to an excellent approximation two small droplets do not interact (i.e. $K_{m,n} \approx 0$) and the first term in (64) can be neglected. Thus Eq.(64) becomes

$$\frac{dS_m}{dt} = \sum_j v_{m,j} = V_m.$$  

(65)

Then a small droplet will live for time

$$t_m = -S_m/V_m.$$  

(66)

Turning now to integrate Eq.(64) we note that the term $v_{i,m}$, which represents the contribution of the fast droplet $m$ to the growth of the slow droplet $i$ is actually present only during the interval $t_m$ and not the entire $\tau$. Hence we must use

$$S_i(t + \tau) = S_i(t) + \left( \sum_j v_{i,j} \right) \tau + \sum_m v_{i,m} t_m$$

which can be rewritten, using Eq.(65), as

$$S_i(t + \tau) = S_i(t) + \left( \sum_j v_{i,j} + \frac{1}{\tau} \sum_m S_m v_{i,m} \right) S_m V_m \tau.$$  

(67)

This is, in fact, the discrete-time form of the differential equation

$$\frac{dS_i}{dt} = \sum_j v_{i,j} + \frac{1}{\tau} \sum_m S_m v_{i,m} V_m.$$  

(68)

This equation has a very simple interpretation: the $i$-th large droplet obtains from each of the small droplets a part of the latter’s area, proportional to the strength of the interaction between the droplets. Eq.(67) is the main working formula of our algorithm. The two terms in the parentheses correspond to (i) redistribution of the material between the large droplets and (ii) absorption of the material that leaves the small droplets onto the large ones. Using Eq.(67) eliminates the fast scale of the dynamics; the time scale $\tau$ is to be chosen so that the assumptions made above are indeed satisfied. Our scheme is put to practice by first choosing a convenient *fraction of small droplets*, which is then kept (approximately) fixed throughout the run (typically we used $f_s \approx 0.003$, that corresponds to removing $\sim 80$ droplets at each time step when the system contains 28000 droplets).

Finally, we should take into account the shift of the droplets. For that one can use either the exact relation

$$\frac{d\hat{r}_i}{dt} = 2 \sum_{j \neq i} \frac{q_j}{|X_{i,j}||X_{i,j}|} \hat{X}_{i,j},$$  

(69)

where the charges $q_i = R_i \dot{R}_i$ are evaluated at each time step, or the heuristic formula

$$\frac{d\hat{r}_i}{dt} = 2 \sum_{j \neq i} \frac{K_{j,i} \left( 1/R_i - 1/R_j \right)}{k_i k_j |X_{i,j}|^2} \hat{X}_{i,j}.$$  

(70)

discussed in the Introduction and Appendix A. Then we proceed according the following steps:
1. Pick $R_s$ such that the number of droplets with $R_n \leq R_s$ is approximately $N_s = f_s N$. (In practice $R_s/(R)$ is kept fixed - in the scaling state this is the same as fixing $f_s$). Identify these as small droplets and calculate all $V_m$ using Eq. (64).

2. An estimate $\tau^{(0)}$ for the time step is determined, as the interval during which all small droplets vanish;

$$\tau^{(0)} = \max_{m}\{t_m\},$$

where $t_m$ is determined by Eq. (66).

3. Calculate the velocities of the large droplets, $V_i = \sum_j v_{i,j}$ (summing over neighbors of $i$ only - hence this step takes $\sim N$ operations). Note that some droplet $i$ which has been classified as "large" may, in fact, disappear during the interval $\tau^{(0)}$; this happens if the velocity is such that $S_i < -V_i\tau^{(0)}$. All such droplets, if any, are collected and reclassified as "small", a new value for $\tau$ is determined and the velocities (both $V_m$ and $V_i$) are recalculated. Usually one such iteration suffices to reach a self-consistent classification.

4. Integrate Eq. (68) one step $\tau$; that is, calculate new areas according to Eq. (71).

5. Calculate the shifts of the droplets according to either Eq. (69) or Eq. (70) and repeat the procedure.

Since the relaxation time needed to reach the scaling state depends on how close the initial configuration is to this state, one would like to choose the initial configuration reasonably close to it. We prepared our initial state as follows. We generated a set of $N = 50000$ droplets with a distribution of radii close to the expected one (determined from short preparatory runs). We scattered them over the plane at random but so that each droplet is surrounded by a small depletion zone (free of other droplets), to mimic the effect of correlations that appear in the real evolving system. For this initial configuration we started a rather large time step $\tau$ (and run the dynamics without moving droplets) yielding only an approximation to the true dynamics. This preliminary relaxation went on till the number of droplets was reduced to $N = 28000$. At this point a smaller time step was selected, the droplets were allowed to move and we started to take measurements. All the results presented below are averaged over 8 runs in order to reduce statistical fluctuations.

In our first simulations we did not take into account the shift of droplets. As is shown in Appendix A, this frozen droplets approximation might be good even for fractions as large as $\varphi = 0.13$. In order to test this, we executed runs with frozen droplets and measured the fraction $f_c$ of droplets crossing each other, as a function of the number of droplets in the system. This data is presented in Fig. 1. It shows a considerable growth of $f_c$ with time (from zero at $N = 28000$ to 10% at $N = 1000$) and there is no tendency towards stabilization. This proves that the droplets’ motion has a considerable effect on the dynamics of the system and, hence, the model of frozen droplets is invalid for such large $\varphi$.

Taking the droplets’ shift into account improves drastically this situation. We used both Eq. (69) and Eq. (70) (called models A and B respectively; see below) for the droplets’ motion. Fig. 1 shows that both models A and B give rise to much smaller values of $f_c$ and that it saturates at long times. Interestingly, while there is no essential difference between these two models, the heuristic model B exhibits slightly lower values of $f_c$ than model A. In order to test the convergence of the sum in Eq. (69) we executed runs with different numbers of terms in the sum taken into account; namely, we varied the size of the summation box from $N = 28000$ to 10% at $N = 1000$ and there is no tendency towards stabilization. This proves that the droplets’ motion has a considerable effect on the dynamics of the system and, hence, the model of frozen droplets is invalid for such large $\varphi$.

We now present results of our simulations, performed at the same relative area fraction, $\varphi = 0.13$, that was studied experimentally. We measured the position correlation function, $G(r)$; that is, the mean number of the droplets whose centers lie within an annulus $[r, r + dr]$ around the center of a given one. Fig. 2 presents $G(r)$ obtained running model B at three consequent moments of time, when the system contained 3000, 2000 and 1000 droplets respectively (each of the curves is averaged over 8 runs). We see that the three curves coincide up to their fluctuations, which proves that the scaling state has indeed been reached. The corresponding experimental data are also presented in this figure; a good agreement is seen. Fig. 3 compares the position correlation functions obtained by the models A and B (averaged over time in the scaling state). This proves that our heuristic formula works perfectly. The experimental $G(r)$ has a noticeable maximum at $r \approx 4.7$, while for our curves the maximum is smaller; at the same time our curve is rather close to the result of Masbaum (see Fig. 1a in ref. [14]), that has a small peak as well, which can not be distinguished clearly from the fluctuations. Note that in ref [14] the data were taken with $N \sim 800$ droplets, whereas our data is well averaged (effectively it corresponds to a system of about 50000 droplets in the scaling state), and the small peak is definitely observed.

Analysis of the distribution of the droplets’ radii at three consequent moments of time, where the system contained 3000, 2000 and 1000 droplets respectively, also shows that the distribution achieved its stationary form. No clear
difference between the models A and B was seen. The droplets’ radii distribution in the scaling state, averaged over
time, as obtained from our simulations (model B), is shown in Fig. 4 together with the experimental results. A certain
discrepancy is seen which, however, does not exceed by much the statistical errors of the experimental points.

Finally, we measured the charge correlation functions $g_\pm(r)$, that contain more detailed information about the system,
defined as follows. For a charge $q_i$ calculate $Q_+(r)$, the total amount of similar charge as $q_i$ within an annulus $[r, r+dr]$ around $\vec{r}_i$ and define the function

$$g_+(r) = \langle q_i Q_+(r) \rangle.$$

Similarly we define $g_-(r)$ in terms of the opposite charges. These two functions, as obtained by simulation of the two models, are presented in Fig. 5 together with the corresponding experimental data by Krichevsky and Stavans. The agreement can be characterized as excellent. Again, there is no noticeable difference between the results of models A and B.

One should notice that our definition of the charge correlation functions $g_\pm(r)$, is not precisely the same as that of ref. Krichevsky and Stavans smeared a droplet’s charge on its perimeter before calculating $Q_\pm(r)$, whereas we assigned a droplet’s charge to it’s center. We believe, however, that the smearing of the charge on the droplet’s perimeter is no more than a way of smoothing the data and there is no essential difference between the two definitions.

V. SUMMARY

Ostwald ripening is the coarsening process, observed during the late stage of the evolution of a two-phase system, where the droplets of the minority phase exchange material by means of diffusion. This process leads towards a scaling state in which the characteristic length scale grows with time according to the scaling law $\bar{R} \sim t^{1/3}$, while all the statistical properties (such as the droplets’ size distribution, position correlation functions etc.), once rescaled, remains fixed.

The problem of calculating these characteristics has been studied in a number of detailed numerical simulations, that take into account all the complicated interactions between the droplets, mediated by the diffusion field. These calculations, although being exact, do not contribute much to a qualitative understanding of the importance of different components of the interaction between the droplets. On the other hand, analytical mean field treatments neglect all spatial effects and seem to be oversimplified.

The aim of this paper was to construct and test a "minimal extension" of the mean field approach, that will take into account spatial effects, keeping only the simplest interaction between the droplets. We calculated analytically an approximate form of these interactions using a mean-field approach. Only pairwise interactions between the droplets were preserved. We proposed a very efficient numerical algorithm, which allows us to follow the evolution of tens of thousands of droplets. We tested our approach by comparing its results with the experimental data and found surprisingly good agreement at a relatively large value of the minority phase area fraction, $\varphi = 0.13$, where our approach to the interaction between the droplets was not expected to work.

Trying to find the simplest model which reproduces the experimental data, we examined the importance of a number of effects. Our findings are summarized as follows:

1. Depletion zones have a considerable effect on the screening length, increasing it from $\zeta = 1.88\bar{R}$ to $\zeta = 2.73\bar{R}$.
   At the same time, as shown in Table I, the presence of the depletion zones almost does not affect the functional form of the pairwise interaction between the droplets.

2. Our approach is based on the assumption of circular droplets and monopole + dipole approximation for the diffusion field. The obtained agreement with the experiment indicates that at the values of $\varphi$ studied higher multipoles can be neglected.

3. Even though inclusion of the depletion zones increases the screening length $\zeta$ too little to provide formal validity to our approximation, our simulations show that it works even for $\varphi = 0.13$.

4. The effect of the droplets’ motion is very important for large area fractions, although, formally, it could be regarded as adiabatically small compared to the droplets growth.

5. The expression that determines the shift of the droplets requires summation over a large number of droplets.
   We propose a much simpler heuristic formula (containing a sum over the nearest neighbors only), that gives even better results than the exact one.
An advantage of our method is its computational efficiency; we are able to choose time steps no smaller than required by physical reasonability, eliminating a large number of droplets at each step. At the same time, the total area of the droplets is conserved exactly at each time step. This makes our approach useful for extensive studies of the Ostwald problem.

APPENDIX: A ANALYSIS OF THE FORMULA FOR THE DROPLETS’ SHIFT.

The droplets’ shifts are determined by Eq.(20):

$$\frac{d\vec{r}_i}{dt} = 2 \sum_{j \neq i} \frac{q_j}{|X_{i,j}|} \frac{X_{i,j}}{|X_{i,j}|}$$  \hspace{1cm} (A1)

First of all, using this formula we can show, that in the low area fraction limit the shift of the positions can be neglected. Indeed, \(\tau_{sh}\), the characteristic time of a shift of a droplet’s center of mass is given by

$$\tau_{sh}^{-1} \sim \frac{1}{X_{i,j}} \left| \frac{dX_{i,j}}{dt} \right| \sim \frac{q_j}{X_{i,j}}.$$  \hspace{1cm} (A2)

The characteristic growth time of the droplet is (see Eq.(12))

$$\tau_{gr}^{-1} \sim \frac{1}{R_i} \left| \frac{dR_i}{dt} \right| \sim \frac{q_i}{R_i^2}.$$  \hspace{1cm} (A3)

Comparing Eqs.(A2) and (A3) we see that

$$\tau_{sh}^{-1} \sim \tau_{gr}^{-1} \frac{R_i^2}{X_{i,j}} = \tau_{gr}^{-1} \frac{\varphi}{\pi}. \quad (A4)$$

That is, for small area fractions the motion of the droplets’ centers is adiabatically slower than their growth. Consequently, one can neglect the droplets’ motion and the system is characterized only by the dynamics of the droplets’ radii as determined by Eq.(13)-(14). Formally, one can expect this approximation to be valid even for \(\varphi = 0.13\) (used in the experiments by Stavans and Krichevsky) and we have tried it in our work (see Section IV and Fig. 1). Our simulations have shown, however, that neglecting the droplets’ motion gives wrong results and, therefore, the dynamics of the \(\vec{r}_i\) has been taken into account.

Secondly, note that a rough estimate of the sum on the r.h. of Eq.(A1) indicates that it exhibits bad convergence properties. Assuming \(q_j\) to be uncorrelated random variables with zero mean we get

$$\left\langle \left( \frac{d\vec{r}_i}{dt} \right) \right\rangle^2 \sim \langle q^2 \rangle \sum_j \frac{1}{|X_{i,j}|^2} \sim \langle q^2 \rangle \log L_s,$$  \hspace{1cm} (A5)

where \(L_s\) is the size of the system. A more accurate treatment implies, however, that the sum does converge. According to Eqs.(12)-(16)

$$q_j = R_j \frac{dR_j}{dt} = \sum_{m(\neq j)} K_{j,m} \Delta_{j,m},$$

where

$$\Delta_{j,m} = \frac{1}{k_m k_j} \left( \frac{1}{R_m} - \frac{1}{R_j} \right)$$

and we use the abbreviations \(K_{j,i} = K_0(X_{j,i}/\zeta_{sc})\), \(k_j = K_0(R_j/\zeta_{sc})\). Then Eq.(A1) becomes:

$$\frac{1}{2} \frac{d\vec{X}_i}{dt} = \sum_{j(\neq i)} Q^{(i)}_j \frac{\vec{X}_{i,j}}{|X_{i,j}|^2} + \sum_j \sum_{m(\neq i)} Q^{(m)}_j \frac{\vec{X}_{i,j}}{|X_{i,j}|^2}, \quad \hspace{1cm} (A6)$$

where

$$Q^{(j)}_i \equiv K_{j,i} \Delta_{j,i}$$

denotes the part of the charge on the \(i\)-th droplet that is induced by the \(j\)-th one. The first term of Eq.(A6) determines the shift of the droplet due to the direct material transfered between this droplet and its \(j\)-th neighbors. This sum
converges very well because $Q^{(j)}_i$ decreases exponentially with distance $X_{i,j}$. The second term accounts for the effect of the redistribution of the material between the $j$-th and $m$-th droplets. Since the internal sum (on $m$) contains a short-range factor $K_{j,m}$, it is actually over a $\zeta \times \zeta$-box around the $j$-th droplet. In this double sum, each term

$$Q^{(m)}_j \frac{\vec{X}_{i,j}}{|X_{i,j}|^2}$$

can be paired with:

$$Q^{(j)}_m \frac{\vec{X}_{i,m}}{|X_{i,m}|^2}.$$  

Since $Q^{(m)}_j = -Q^{(j)}_m$, these two contributions can be considered as a dipole. Thus, each $\zeta \times \zeta$-box represents a dipole $\vec{P}$ (randomly directed) with the dipole moment $P \sim q\zeta$, where $q$ is the characteristic scale of $Q^{(j)}_m$. Thus, the second term in Eq.(A6) is now estimated as:

$$\text{second term} \sim \sum_{\zeta \times \zeta-\text{boxes}} \frac{\vec{P}}{|X_{i,j}|^2} - \frac{2(\vec{P} \cdot \vec{X}_{i,j})\vec{X}_{i,j}}{|X_{i,j}|^4} \sim \sum \frac{\vec{P}}{|X_{i,j}|^2}. \quad (A7)$$

The mean of this expression is zero while the mean square deviation is given by

$$\sim q^2 \zeta^2 \sum \frac{1}{|X_{i,j}|^4}, \quad (A8)$$

which converges to a finite value. Thus, when calculating the sum in Eq.(A1), we can restrict ourselves to only several nearest layers of neighbors.

Finally, one can use an even simpler heuristic formula for calculating the shift of the droplets. The meaning of Eq.(A6) is that the motion of $i$-th droplet has two sources. The first is the material transferred between this droplet and its $j$-th neighbors (the first term of Eq.(A6)). The second is due to redistribution of the material between the surrounding $j$-th droplets themselves (the second term). Although these contributions are of the same order, in our case we have a reason to drop the second term (although it does not simplify computations, it does make the model physically simpler). The shift of the droplets has a noticeable effect only at relatively large fractions, where the interaction between the next nearest neighbors is considerably suppressed. Then, for a fixed configuration of the nearest neighbors of the $i$-th droplet we can vary the configuration of its next nearest neighbors. This manipulation will not affect the first term of the Eq.(A6), while it will reduce its second term. Thus, in the mean field spirit of our model, we can average the shift velocity of the $i$-th droplets over various configurations of its next nearest neighbors. Thus, we finally get:

$$\frac{d\vec{X}_{i}}{dt} = 2 \sum_{j \neq i} \frac{K_{j,i}}{k_i k_j} \left( \frac{1}{R_i} - \frac{1}{R_j} \right) \frac{\vec{X}_{i,j}}{|X_{i,j}|^2}. \quad (A9)$$

Although the approximation leading to this formula is not based on a rigorous expansion, our simulations show that it works as well as the more rigorous Eq.(A1). At the same time it is much more economic because it requires the summation only over the nearest neighbors.
APPENDIX: B DEPLETION ZONES

The simplest possible improvement over the mean-field approximation can be obtained by including some of the correlations between the positions of the droplets’ centers. In this Appendix we will take into account the simplest manifestation of these correlations — the so-called depletion zones. These are the regions around each of the droplets, from which all possible neighbors are excluded (by geometrical steric constraints - the distance between the centers of any two droplets must exceed at least the sum of their radii).

The exact equation for the diagonal elements of the matrix $\hat{\phi}$ is given by Eq.(41), whereas for the off-diagonal elements it is Eq.(39)

$$\sum_{j \neq i,k} \frac{1}{\log R_j/R_0} \log(X_{i,j}/R_0) \phi_{j,k} + \phi_{i,k} = -\gamma_k \log X_{i,k}/R_0. \quad (B1)$$

This has been replaced in our mean field approximation by the following integral equation for the smooth function $\phi(x)$ (see Eq.(45)):

$$-\frac{1}{2\pi \zeta_0^{-2}} \int \log(X_{i,j}/R_0) \phi(X_{j,k})d^2r_j + \phi(X_{i,k}) = -\gamma \log X_{i,k}/R_0. \quad (B2)$$

Clearly, by using the integral of Eq.(B2) we implicitly assume that the distribution of $r_j$, the positions of the centers of droplets $j$, are independent of their distance from the one at $r_i$. This homogeneity assumption may serve as a reasonable approximation as long as $X$, the mean distance between neighbors, is much greater than $d$, the typical radius of the depletion zones. When, however, the density increases to the extent that $X \sim d$, the inhomogeneity of the distribution of the $j$-droplets around the fixed droplets $i$ and $k$ can no longer be ignored. One should emphasize that other effects, such as correlations between different "charges" and between the droplets' sizes may also be of importance and can also possibly affect the elements of the inverse matrix we are calculating. Nevertheless, here we take into account only the correlations that ensure that the areas of two neighbors do not overlap. In our actual numerical calculations even this is done only approximately, by introducing a uniform sized depletion zone, neglecting its fluctuations as well as dependence on the droplets’ radii.

Correlation between the positions of the droplets can be incorporated in our approximate treatment by replacing the sum in Eq.(31) by the following integral operator:

$$\hat{S}_{\text{int}} \phi = -\frac{1}{2\pi \zeta_0^{-2}} \int \log(X_{i,j}/R_0) P(\bar{r}_i, \bar{r}_j, \bar{r}_k) \phi(X_{j,k})d^2r_j, \quad (B3)$$

where $P(\bar{r}_i, \bar{r}_j, \bar{r}_k) = g(X_{i,j})g(X_{j,k})$, $g(r) \rightarrow 1$ at $r \rightarrow \infty$. Within this approximation Eq.(B1) is replaced by

$$\hat{S}_{\text{int}} \phi + \phi(X_{i,k}) = -\left(1 + \frac{\phi_{k,k}}{\log(R_k/R_0)}\right) \log X_{i,k}/R_0 \quad (B5)$$

where now we have

$$\hat{S}_{\text{int}} \phi = -\frac{1}{2\pi \zeta_0^{-2}} \int \log(X_{i,j}/R_0) g(X_{i,j})g(X_{j,k})\phi(X_{j,k})d^2r_j. \quad (B6)$$

In order to solve equation (B5) we first try to bring it as close to the form of Eq.(B2), as we can, and then use the same method of solution as was used there. To this end we first rewrite the expression for $\hat{S}_{\text{int}}$ as follows:

$$\hat{S}_{\text{int}} \phi = -\frac{1}{2\pi \zeta_0^{-2}} \int \log(X_{i,j}/R_0) g(X_{i,j})\phi(X_{j,k})d^2r_j$$

$$+ \frac{1}{2\pi \zeta_0^{-2}} \int \log(X_{i,j}/R_0) g(X_{i,j})[1 - g(X_{j,k})]\phi(X_{j,k})d^2r_j. \quad (B7)$$
The pair correlation function \( g(X) \) vanishes for short distances, \( X < d \), and \( g \approx 1 \) for large \( X \). Therefore, we get non-vanishing contributions to the second term in Eq. (B7) only when \( X_{i,k} < d \). For \( X_{i,k} \gg d \), we have in this region \( g(X_{i,j}) \approx 1 \) and \( \log(X_{i,j}/R_0) \approx \log(X_{i,k}/R_0) \), so that

\[
\hat{S}_{\text{int}} \hat{\phi} \approx -\frac{1}{2\pi} \int \log(X_{i,j}/R_0)g(X_{i,j})\phi(X_{j,k})d^2r_j
- \frac{1}{2\pi} \zeta_0^{-2} \log(X_{i,k}/R_0) \int [1-g(X_{i,j})]\phi(X_{j,k})d^2r_j. \tag{B8}
\]

The last formal step we take is to express the first integral here as the sum of two terms, using \(-g = [1-g] - 1\), which leads to our final expression for \( \hat{S}_{\text{int}} \hat{\phi} \):

\[
\hat{S}_{\text{int}} \hat{\phi} = -\frac{1}{2\pi} \zeta_0^{-2} \int \log(X_{i,j}/R_0)\phi(X_{j,k})d^2r_j
+ \frac{1}{2\pi} \zeta_0^{-2} \int \log(X_{i,j}/R_0)[1-g(X_{i,j})]\phi(X_{j,k})d^2r_j
- \frac{1}{2\pi} \zeta_0^{-2} \log(X_{i,k}/R_0) \int [1-g(X_{i,j})]\phi(X_{j,k})d^2r_j. \tag{B9}
\]

Our basic equation (B3) takes now the form

\[
-\frac{1}{2\pi} \zeta_0^{-2} \int \log(X_{i,j}/R_0)\phi(X_{j,k})d^2r_j + \phi(X_{i,k}) + \frac{1}{2\pi} \zeta_0^{-2} \int F(X_{i,j})\phi(X_{j,k})d^2r_j
= -\gamma_k \log(X_{i,k}/R_0), \tag{B10}
\]

where

\[
\gamma_k = 1 + \frac{\phi_{k,k}}{\log(R_0/R_k)} + \frac{1}{2\pi} \zeta_0^{-2} \int (1-g(X_{j,k}))\phi(X_{j,k})d^2r_j \tag{B11}
\]

and

\[
F(X) = \log(X/R_0)[1-g(X)]. \tag{B12}
\]

Note that equation (B10) is very close in form to Eq. (B3): the only significant difference being the appearance of a new term - the integral over the function \( F \), which contains explicitly the correlation function \( g \). Clearly when \( g(X) \equiv 1 \) we recover Eq. (B2). As was the case there, the solution of Eq. (B10) is symmetric if and only if \( \gamma_k \) does not depend on \( k \). \( \gamma_k \approx \gamma \), which is achieved by imposing \( \phi_{k,k} = 0 \). This leads again to a condition that determines the value of the parameter \( R_0 \) (see Eq. (B2) below). Although now \( \gamma \neq 1 \) (see Eq. (B11)), its value is unimportant for the simulations since it can be absorbed in the definition of the time scale in the dynamic equation. Hence below we will set \( \gamma = 1 \).

We solve Eq. (B10) by first applying the \( \nabla_i^2 \) operator to the equation, which yields

\[
-\zeta_0^{-2}\phi(X_{i,k}) + \nabla_i^2\phi(X_{i,k}) + \frac{1}{2\pi} \zeta_0^{-2} \int F(X_{i,j})\phi(X_{j,k})d^2r_j
= -2\pi \gamma \delta(X_{i,k}). \tag{B13}
\]

Denote the Fourier transform of \( F(X) \) by

\[
\tilde{F}(q) = \frac{1}{2\pi} \int d^2r \log \left( \frac{r}{R_0} \right) [1-g(r)]e^{iq \cdot r}
= \int_0^\infty rdr \log \left( \frac{r}{R_0} \right) [1-g(r)]J_0(qr). \tag{B14}
\]

Note that the integral converges, since \( g(r) \to 0 \) fast for large \( r \). Upon Fourier transforming Eq. (B13) becomes

\[
-\zeta_0^{-2}\tilde{\phi}(q) - q^2\tilde{\phi}(q) - \zeta_0^{-2} q^2 \tilde{F}(q)\tilde{\phi}(q)
= -2\pi \gamma \tilde{\phi}(q) \quad \text{for large } q \tag{B15}
\]

yielding the solution for \( \tilde{\phi}(q) \) (from now on we set \( \gamma = 1 \))
\[ \tilde{\phi}(q) = \frac{2\pi}{q} \frac{1}{1 + \zeta_0^{-2} \left[ F(q) + q^{-2} \right]} \].

Once \( \tilde{\phi}(q) \) has been evaluated, the function \( \phi(X) \) is obtained by the inverse Fourier transform. From this point on we work with the specific (step-function) form of \( g(X) \):

\[ g(X) = \begin{cases} 0 & X < d \\ 1 & X > d \end{cases} \]

For this form of \( g \) the integral in Eq. (B14) can be calculated analytically, integrating by parts and using the identities \( xJ_1(x)' = xJ_0(x) \) and \( J_0(x)' = J_1(x) \), to get

\[ F(q) = q^{-2} \left\{ -qJ_1(qd) \log (R_0/d) + [1 - J_0(qd)] \right\}. \]  

We now substitute this in (B16) and perform the angular integration in the inverse Fourier transform, to arrive at the following expression for \( \phi(r) \):

\[ \phi(r) = \int_0^\infty \frac{J_0(qr)}{q^2 + \zeta_0^{-2} - \left[ \zeta_0^{-2} \log (R_0/d) \right] qJ_1(qd) + \zeta_0^{-2} [1 - J_0(qd)]} dq. \]  

We cannot perform this integral analytically, but it is simple to evaluate by numerical integration. Once this has been done, the parameter \( R_0 \) can be found by imposing the condition \( \phi_{k,k} = 0 \), which takes the form (analogous to Eq. (B1))

\[ \phi_{k,k} = \frac{1}{2\pi} \zeta_0^{-2} \int \log \left( \frac{r}{R_0} \right) g(r) \phi(r) d^2 r = 0 \]  

which becomes the following equation for \( R_0 \):

\[ \log R_0 = \frac{\int_0^\infty \log(r) \phi(r) rdr}{\int_0^\infty \phi(r)rdr} \]  

Once \( R_0 \) has been determined we can evaluate the parameter \( \zeta_0 \), using its definition

\[ \zeta_0^{-2} = 2\pi n \left( \frac{1}{\log (R_0/R_i)} \right) \]  

For a given droplet configuration one can now proceed to find \( \phi(r) \) by taking the following steps. First, determine the radius of the depletion zone \( d \) from the measured correlation function of the droplets (such as Fig. 3). Then solve Eqs. (B19) and (B21). This can be done iteratively by initializing the procedure using the results of the correlation-free theory for \( \phi, \zeta_0 \) and \( R_0 \). The next iterate of \( \phi(r) \) is evaluated using Eq. (B19); this new \( \phi(r) \) is then used in Eq. (B21) to yield the new value of \( R_0 \); this, in turn, is used in Eq. (B22), together with the distribution of the droplets’ radii, to yield the new iterate of \( \zeta_0 \). The procedure is then repeated until convergence is reached. In practice we used a few simplifying steps, which made computation faster without significantly altering the result. The first simplification consists of setting

\[ d = \kappa \langle R \rangle \]

for an entire run, instead of determining it from the correlation function at each time step. We found that values in the range \( 2.0 \leq \kappa \leq 2.8 \) fit the correlation function quite well. The numerical results were obtained using the fixed value \( \kappa = 2.15 \). A second time-saving simplification is to use the approximation

\[ \zeta_0^{-2} = 2\pi n \left( \frac{1}{\log (R_0/R_i)} \right) \]  

to calculate \( \zeta_0 \), instead of evaluating the average \( \langle 1/\log (R_0/R_i) \rangle \) over the measured distribution of droplet sizes. Recall also that the density of droplets, \( n \), is related to their relative area fraction, \( \varphi \), by \( n = \varphi/\pi \langle R^2 \rangle \). In the spirit of the previous approximation we replace \( \langle R^2 \rangle \approx \langle R \rangle^2 \), so that Eq. (B24) becomes

\[ \zeta_0^{-2} = \frac{2\varphi}{\langle R \rangle^2 \log (R_0/R_i)} \]  

20
Using Eqs. (B23) and (B25) simplifies our numerical scheme significantly. To demonstrate the effect of including the depletion zones in the calculation we present in Table I the results of calculations performed in the scaling regime at four different values of \( \varphi \). The various quantities presented were obtained as follows: \( R_0 \) and \( \zeta_0 \) are (simultaneous) solutions of Eqs. (B19), (B21) (with \( d = 2.15(R) \) in both) and (B25). \( \zeta_0^{mf} \) is the value of the screening length as obtained by setting \( d = 0 \). The screening length \( \zeta_{scr} \) is the first moment of the function \( \phi(r) \),

\[
\zeta_{scr}^2 = \int_0^\infty \phi(r) r dr
\]

calculated by numerical integration of Eq. (B19).

As we see, for very small fractions the screening length is less than \( \zeta_0^{mf} \). This is surprising, since we expected inclusion of the depletion zones to increase the screening regions. For the larger fractions, however, we indeed see that the effect of including the depletion zone changes sign: the renormalized screening length becomes greater than the mean field result, as was expected.

Another important observation we should make is that as \( \varphi \) increases, \( \zeta \) decreases and becomes comparable to the average radius (in units of which it is given in Table I). At such \( \varphi \), \( \zeta \) obviously cannot be interpreted as a "screening length", because \( \zeta \approx \langle R \rangle \) means that there are no droplets in the "screening zone".

Another question that we studied in detail concerns the extent to which introducing the depletion zone affects the function \( \phi(r) \). Clearly, when we are not in the limit of very small \( \varphi \) it is no longer given by the MacDonald function. Table II contains \( \phi(r) \), as obtained at \( \varphi = 0.13 \) by the procedure outlined above: setting \( d = 2.15(R) \), and simultaneously solving Eqs. (B19), (B21) and (B25). Comparing \( \phi(r) \) with the simple mean-field result \( K_0(r/\zeta_0^{mf}) \) reveals that the renormalization due to inclusion of the depletion zones leads to significant change of the matrix elements \( \phi(r) \). On the other hand, comparing \( \phi(r) \) with the function \( K_0(r/\zeta_0) \) we see that \( \phi(r) \) does not differ much from MacDonald’s function, provided the renormalized \( \zeta_0 \) is used. Therefore in principle this function can be used in calculations as a fairly good approximation for \( \phi(r) \). The numerical results presented in Section IV were obtained using \( \zeta_0 = 2.73 \), according to Table I.

**APPENDIX: C DERIVATION OF THE CONDITION FOR \( R_0 \).**

The condition (45) on \( R_0 \):

\[
\frac{1}{2\pi} \zeta_0^{-2} \int \log(X_{k,j}/R_0) K_0(X_{j,k}/\zeta_0) d^2 r_j = 0
\]

can be simplified by representing

\[
\log(X_{i,j}/R_0) = \log(X_{i,j}/\zeta_0) + \log(\zeta_0/R_0)
\]

so that Eq. (C1) becomes

\[
B + A \log(\zeta_0/R_0) = 0
\]

where the constant \( A \) has the value

\[
A = \frac{1}{2\pi} \zeta_0^{-2} \int K_0(X_{j,k}/\zeta_0) d^2 r_j = 1
\]

because of the normalization of \( K_0(x) \), while the other constant, \( B \), is given by

\[
B = \frac{1}{2\pi} \zeta_0^{-2} \int \log(X_{k,j}/\zeta_0) K_0(X_{j,k}/\zeta_0) d^2 r_j
\]

In order to evaluate \( B \) we note that the solution of Eq. (43) is given, for any value of \( R_0 \), by Eq. (48). Therefore we can substitute \( \phi(X_{i,k}) \) from Eq. (48) in Eq. (45) and choose for \( R_0 \) the special value \( R_0 = \zeta_0 \), to get the identity

\[
- \frac{1}{2\pi} \zeta_0^{-2} \int \log(|\vec{r} - \vec{r}'|/\zeta_0) K_0(r'/\zeta_0) d^2 r' + K_0(r/\zeta_0) = - \log(r/\zeta_0)
\]

It is trivial to see that in the limit \( \vec{r} \to 0 \) the integral on the l.h.s. of this identity becomes precisely equal to \( B \) (as given by Eq. (C4)). For \( \vec{r} \to 0 \) we can use the small \( r \) limit (49) of \( K_0 \) so that for very small \( r \) our identity becomes
\[-B - \log \left( \frac{r}{2\zeta_0} \right) - C = - \log \left( \frac{r}{\zeta_0} \right)\]

so that we find

\[B = \log 2 - C\]  \hspace{1cm} (C6)

(C is Euler’s constant). Using the values of \(A\) and \(B\) in Eq. (C2) it becomes

\[\log 2 - C + \log(\zeta_0/R_0) = 0\]  \hspace{1cm} (C7)

providing a new connection between \(R_0\) and \(\zeta_0\). This is to be used together with Eq. (46) to solve for both \(R_0\) and \(\zeta_0\). Since Eq. (46) contains \(\log(\langle R \rangle/R_0)\), it is convenient to add and subtract \(\log \langle R \rangle\) from Eq. (C7) and to rewrite it as

\[\log(R_0/\langle R \rangle) = \log(2\zeta_0/\langle R \rangle) - C\]  \hspace{1cm} (C8)

If we have \(\langle R \rangle \ll \zeta_0\) the right hand side of Eq. (C8) is \(\approx K_0(\langle R \rangle/\zeta_0)\), so that (C7) becomes \(\log(R_0/\langle R \rangle) \approx K_0(\langle R \rangle/\zeta_0)\). Finally, we can write, with the same accuracy:

\[\left\langle \frac{1}{\log(R_0/R)} \right\rangle \approx \left\langle \frac{1}{K_0(R/R_0)} \right\rangle .\]  \hspace{1cm} (C9)

\section*{APPENDIX: D THE SMALL PARAMETER OF THE APPROXIMATION.}

In the mean field limit, when \(R_0 \sim \zeta_0 \gg R_i\) the quantity \(1/\log(R_0/R_i)\) does not vary much and one can take it out of the sum and replace it by its mean value. Secondly, we see that there is a scale \(\zeta_0\) such that \(\phi\) does not change much over distances much less than \(\zeta_0\). Let us divide the plane into boxes \(b\) of size \(\zeta_0 \times \zeta_0\). Then the sum that still remains can be rewritten as

\[\sum_{j \neq i,k} \log(X_{i,j}/R_0)\phi_{j,k} = \sum_{b \in b, j \neq i,k} \log(X_{i,j}/R_0)\phi_{j,k}\]  \hspace{1cm} (D1)

Actually, only the few boxes located near \(\vec{r}_k\) have a significant contribution to the sum; the contribution of all the others is exponentially small due to the screening effect.

The expression being summed does not change much inside each box and therefore, if the mean number of the droplets in the box, \(N_\zeta\), is large enough, the internal sum within each box can be replaced by the integral. In this case, according to the theorem of large numbers

\[\left| \sum_{j \in b} \log(X_{i,j}/R_0)\phi_{j,k} - n \int \log(X_{i,j}/R_0)\phi(X_{j,k})d^2r_j \right| \sim \frac{1}{\sqrt{N_\zeta}}.\]  \hspace{1cm} (D2)

This gives rise to the following condition for the validity of our approximation:

\[N_\zeta = n\zeta_0^2 \gg 1\]  \hspace{1cm} (D3)

But Eq. (46) implies that \(n\zeta_0^2 \sim (2\pi)^{-1} \log(R_0/\langle R \rangle)\) and, as we have shown \(\zeta_0 \approx R_0\), so that

\[n\zeta_0^2 \sim \log(\zeta_0/\langle R \rangle)\]  \hspace{1cm} (D4)

On the other hand, multiplying Eq. (46) by \(\langle R \rangle^2\) and using the definition of the area fraction \(\varphi = \pi n \langle R^2 \rangle \sim \pi n \langle R \rangle^2\) yields \(\log(\zeta_0/R_0) \sim \log(\varphi^{-1})\). This, together with Eqs. (D3-D4) means that

\[\log(\varphi^{-1}) \gg 2\pi.\]
TABLE I. Various quantities related to the self consistent determination of $\phi(r)$ (with the depletion zones taken into account) for different area fraction $\varphi$. $R_0$ and $\zeta_0$ are (simultaneous) solutions of Eqs. (B19, B21) (with $d = 2.15(R)$ in both) and (B25); $\zeta_{mf}$ is the value of the screening length as obtained in the Section III (neglecting the effect of the depletion zones); $\zeta_{scr}$ is determined by Eq. (B26) with $\phi(r)$ obtained by numerical integration. All lengths are given in units of $\langle R \rangle$.

| $\varphi$ | $R_0$  | $\zeta_{mf}$ | $\zeta_0$ | $\zeta_{scr}$ |
|----------|--------|--------------|-----------|--------------|
| 0.001    | 51.35  | 45.99        | 45.96     | 45.922       |
| 0.01     | 15.59  | 11.77        | 12.13     | 11.71        |
| 0.05     | 8.10   | 4.08         | 4.73      | 4.00         |
| 0.13     | 6.14   | 1.88         | 2.73      | 1.94         |

TABLE II. Interaction function $\phi(r)$ for the case of depletion zones calculated at the area fraction $\varphi = 0.13$. It is compared with the MacDonald’s function with the renormalized screening parameter $\zeta_0$ (third column), and with the unrenormalized, mean-field screening length $\zeta_{mf}$ (fourth column). Note that the distance $r$ is measured in units of the mean distance between neighbor droplets, $x = 1/\sqrt{n}$.

| $r/x$ | $\phi(r)$ | $K_0(r/\zeta_0)$ | $K_0(r/\zeta_{mf})$ |
|-------|-----------|------------------|---------------------|
| .722  | 2.884     | 2.617            | 1.205               |
| .884  | 1.914     | 1.773            | .711                |
| 1.045 | 1.320     | 1.218            | .425                |
| 1.206 | .901      | .845             | .257                |
| 1.420 | .546      | .525             | .133                |
| 1.689 | .297      | .294             | .059                |
| 1.904 | .185      | .186             | .031                |
| 2.012 | .147      | .148             | .022                |
| 2.118 | .118      | .118             | .016                |
| 2.333 | .075      | .076             | .008                |
| 2.548 | .046      | .048             | .004                |
| 2.763 | .027      | .031             | .002                |
| 2.97  | .016      | .020             | .001                |
| 3.031 | .014      | .018             | .001                |
| 3.353 | .0087     | .0095            | .00047              |
FIG. 1. Time dependence of $f_c$, the fraction of crossing droplets, as obtained from the frozen droplets model (empty squares); from model B, that uses the heuristic Eq. (70) for the droplets' shift (full squares) and from model A, that uses the exact Eq. (69) for the droplets shift (large circles and small circles for small and large summation block sizes: $b = 4.1\zeta$ and $b = 5.8\zeta$ respectively; see explanations in text). The lines are guides for eye. The growth of $f_c$ observed for the frozen droplets model indicates that it is not valid for the area fraction $\varphi = 0.13$. On the other hand, once the droplets are allowed to move, $f_c$ decreases to very small values irrespective of whether model B or A is used.
FIG. 2. Correlation functions of droplets' positions, $G(r)$, as measured at different moments of time in the scaling state, corresponding to $N = 3000$, $N = 2000$, $N = 1500$, $N = 1300$, $N = 1000$ droplets present (small circles). The weighted average of these runs (the weight of a configuration is proportional to the corresponding number of droplets) is also shown (large circles). These results were obtained using model B. Note that all the lines are close to each other, indicating that system has indeed arrived at the scaling state. The experimental results of Krichevsky and Stavans, shown for comparison (squares), are also close to ours.
FIG. 3. Weighted time average (the weight of a configuration is proportional to its number of droplets) of the correlation functions of droplets’ positions, $G(r)$, (averaged over 8 runs) for models A and B in the scaling state (large circles and small circles respectively). The experimental results of Krichevsky and Stavans are also shown (squares). This shows that the two models give indistinguishable results that are in good agreement with experiment as well.
FIG. 4. \( Y(R) \), the droplets’ rescaled size distribution in the scaling state at \( N = 3000 \) (largest circles), \( N = 2000 \) (intermediate circles) and \( N = 1000 \) (small circles). Each plot presents the average over 8 runs. The line indicates the overall average. The experimental results of Krichevsky and Stavans are also shown (diamonds).
FIG. 5. The charge correlation functions (see precise definition in the text) for the same ($g_+(r)$) and the opposite ($g_-(r)$) charges, as obtained using models A and B, compared with the experimental data of Krichevsky and Stavans (full circles and full squares for the same and the opposite charges respectively). The lines are the guides for eye. Our data present averages over 8 runs. Note that the fluctuations in this plot are larger than for the position correlation function (see Fig. 2). We believe that the difference between the results of the two models is due to the fluctuations. Interestingly, model B seems to be closer to the experimental points.

When fluctuations in $R_j$ are neglected, this equals $1/\log((R_j)/R_0)$.

The role of the parameter $R_0$ in our theory is analogous to the parameter $\Delta$ in Beenakker’s model\textsuperscript{20}; while being irrelevant for the exact problem, it was tuned in order to restore conservation of material, broken in the reduced description.
