(Dated: January 31, 2013)

We investigate the entanglement properties of the valence-bond-solid (VBS) state defined on two-dimensional lattices, which is the exact ground state of the Affleck-Kennedy-Lieb-Tasaki (AKLT) model. It is shown that the entanglement entropy obeys an area law and the non-universal prefactor of the leading term is strictly less than \( \ln 2 \). The analysis of entanglement spectra for various lattices reveals that the reduced density matrix associated with the VBS state is closely related to a thermal density matrix of a holographic spin chain, whose spectrum is reminiscent of that of the spin-1/2 Heisenberg chain. This correspondence is further supported by comparing the entanglement entropy in the holographic spin chain with conformal field theory predictions.

I. INTRODUCTION

There has been considerable recent interest in understanding quantum entanglement in many-body systems. Entanglement (von Neumann) entropy and the family of Rényi entropies are often used to quantify the degree of entanglement of a bipartite system consisting of two subsystems \( A \) and \( B \). However, as pointed out by Li and Haldane, the entanglement spectrum (ES), the eigenvalue spectrum of the reduced density matrix (RDM) of either system \( A \) or \( B \), provides a more complete description of the ground state and the low-energy states of the system. In general, the RDM for \( A \) may be written as \( \rho_A = \exp(-H_E) \) with the entanglement Hamiltonian \( H_E \). Li and Haldane demonstrated that the spectrum of \( H_E \) for fractional quantum Hall states on a sphere reflects the gapless edge excitations in the disk geometry. Since then, the ES has been applied to other systems such as topologically ordered systems and quantum spin models, and the entanglement gap was proposed as a non-local order in gapless spin chains.

Although the analysis of the ES has turned out to be a powerful tool to extract universal properties, the application has so far been limited to one-dimensional (1D) or topological systems. To fill this gap in the literature, we examine the ES in the two-dimensional (2D) quantum spin model proposed by Affleck, Kennedy, Lieb, and Tasaki (AKLT). The AKLT model in one dimension was first introduced as a solvable model to illustrate the Haldane-gap phase in integer spin chains. The exact ground state is known as the valence-bond-solid (VBS) state. The construction of the VBS state generalizes to ground state is known as the valence-bond-solid (VBS) state. The organization of the rest of the paper is as follows. In Sec. II, we first review the construction of the VBS state on the hybrid lattice consisting of squares and hexagons, we find that the ES is \( gapped \) and \( H_E \) is close to the alternating Heisenberg chain in which ferromagnetic and antiferromagnetic interactions are mixed.

The organization of the rest of the paper is as follows. In Sec. II, we first review the construction of the VBS state on the hybrid lattice consisting of squares and hexagons, we find that the ES is \( gapped \) and \( H_E \) is close to the alternating Heisenberg chain in which ferromagnetic and antiferromagnetic interactions are mixed.

In this paper, we study numerically the ES in the 2D AKLT model defined on various lattices. We develop an efficient way to evaluate the RDM using a Monte Carlo (MC) method. The ES is then obtained by numerical diagonalization. It is shown that the ES is not \( \text{flat} \) in 2D, which is in contrast to the 1D case where all eigenvalues of the RDM become degenerate in the thermodynamic limit. When a system is on a cylinder, we can study the ES as a function of momentum. The low-lying spectrum of the entanglement Hamiltonian \( H_E \) for square (hexagonal) VBS state is reminiscent of that of the 1D antiferromagnetic (ferromagnetic) Heisenberg chain. This indicates that the entanglement Hamiltonian \( H_E \) is very close to the Heisenberg Hamiltonian in one dimension. To further support this idea, we introduce a new concept, nested entanglement entropy (NEE), and find that, for the square lattice VBS state, the low-energy effective Hamiltonian of \( H_E \) is well described by \( c = 1 \) conformal field theory (CFT) despite that the starting quantum state (the AKLT state in this paper) is not critical. For a hybrid system consisting of squares and hexagons, we find that the ES is \( gapped \) and \( H_E \) is close to the alternating Heisenberg chain in which ferromagnetic and antiferromagnetic interactions are mixed.
II. 2D VBS STATES

A. AKLT Hamiltonian

We study the AKLT model on the square and hexagonal lattices shown in Fig. 1 (a). For simplicity, we focus on the basic model in which there is a single valence bond on each edge. The spin-S Hamiltonian for this model is written as a sum of projection operators as

\[ H = \sum_{(i,j)} A(i,j) \tau_{2S}(i,j), \]

where \( A(i,j) \) is an arbitrary positive number and \( \tau_{2S}(i,j) \) projects the total spin of each pair of neighboring spins onto the subspace of \( J = 2S \). The spin magnitude \( S \) and the coordination number \( z \) are related through \( z = 2S \), where \( z = 4 \) for the square lattice, while \( z = 3 \) for the hexagonal lattice. The unique ground state (VBS state) of \( H \) is written as

\[ |\Psi\rangle = \prod_{(i,j)} (a_i^+ b_j^+ - b_i^+ a_j^+)|\text{vac}\rangle, \]

where \( a_i^+ \) and \( b_i^+ \) are Schwinger bosons at site \( i \), satisfying

\[ [a_i, a_j^+ ] = [b_i, b_j^+ ] = \delta_{i,j} \]

with all other commutators vanishing, and \( |\text{vac}\rangle \) denotes the vacuum state. With the constraint that the total number of bosons at each site is \( 2S \), the original spin operators can be represented by the Schwinger bosons as

\[ S_i^+ = a_i^+ b_i, \quad S_i^- = b_i^+ a_i, \quad S_i^z = \frac{1}{2}(a_i^+ a_i - b_i^+ b_i). \]

We will study VBS states defined on lattices with both periodic (PBC; cylindrical geometry) and open (OBC; rectangular geometry) boundary conditions shown in Fig. 1 (b).

![FIG. 1: (Color online) (a) VBS states on the square and hexagonal lattices with reflection symmetry. Lattice is separated into two subsystems A and B by the reflection axis (the dotted line). The bulk width is denoted by \( L_x \), while the number of bonds on the boundary is \( L_y \). Notice that in the hexagonal lattice, \( L_x \) is defined as half the number of sites along the \( x \)-axis. In both cases, \( L_x = 3 \) and \( L_y = 4 \). (b) Boundary conditions. Upper and lower panels show cylindrical (PBC) and rectangular (OBC) geometries, respectively.](image)

B. Reduced density matrix

Let us consider a bipartition into two subsystems \( A \) and \( B \), each of which is a mirror image of the other, and the boundary between them is chosen to be the reflection axis. We denote the bulk width of \( A \) (\( B \)) by \( L_x \) and the number of bonds on the boundary by \( L_y \). The Hamiltonian can be written in the form \( H = H_A + H_B + H_{AB} \), where \( H_A \) and \( H_B \) denote the Hamiltonians within subsystems \( A \) and \( B \), respectively, while \( H_{AB} \) contains all the interactions across the boundary. The RDM for \( A \) describing the entanglement between the two subsystems is defined by \( \rho_A = \text{Tr}_B[|\Psi\rangle \langle \Psi|]/N \), where \( N = \langle \Psi | \Psi \rangle \). To obtain the spectrum of \( \rho_A \), we follow the same approach used in Ref. [22]. The ground state of the system can be written as

\[ |\Psi\rangle = \sum_\alpha |\phi_\alpha^{[A]} \rangle \otimes |\phi_\alpha^{[B]} \rangle, \]

where \( \alpha = 1, 2, \ldots, 2^{L_y} \) and \{\( |\phi_\alpha^{[A]} \rangle \} \{\langle \phi_\alpha^{[B]} | \} \) is a set of degenerate ground states of \( H_A \) \( (H_B) \), each of which is characterized by a configuration of bosons at the boundary sites. These states are linearly independent but not orthogonal. We now introduce overlap matrices as

\[ M^{[A]}_{\alpha\beta} = \langle \phi_\alpha^{[A]} | \phi_\beta^{[A]} \rangle, \quad M^{[B]}_{\alpha\beta} = \langle \phi_\alpha^{[B]} | \phi_\beta^{[B]} \rangle \]

for two subsystems, respectively. Due to the reflection symmetry, one can show that \( M^{[A]} = M^{[B]} = M \) and \( M \) is real symmetric and positive definite. One can then construct the orthonormal states out of \{\( |\phi_\alpha^{[A]} \rangle \} \{\langle \phi_\alpha^{[B]} | \} \) using an orthogonal matrix \( O \) that diagonalizes \( M \), i.e.,

\[ O^T MO = \text{diag}(d_1, d_2, \ldots, d_{2^{L_y}}) \]

\[ |\psi_\alpha^{[A]} \rangle = \frac{1}{\sqrt{d_\alpha}} \sum_\beta O_{\alpha\beta} |\phi_\beta^{[A]} \rangle, \]

\[ |\psi_\alpha^{[B]} \rangle = \frac{1}{\sqrt{d_\alpha}} \sum_\beta O_{\alpha\beta} |\phi_\beta^{[B]} \rangle. \]

The ground state of the full system in the new basis is written in the Schmidt decomposition as

\[ |\Psi\rangle = \sum_\alpha d_\alpha |\psi_\alpha^{[A]} \rangle \otimes |\psi_\alpha^{[B]} \rangle, \]

and hence \( \rho_A = \sum_\alpha d_\alpha^2 |\psi_\alpha^{[A]} \rangle \langle \psi_\alpha^{[A]} |/N \). Therefore, the spectrum of \( \rho_A \) is equivalent to that of the following matrix

\[ \hat{\rho}_A = \frac{M^2}{\text{Tr}(M^2)}, \]

where \( \text{Tr} \) denotes the standard matrix trace (not to be confused with \( \text{Tr}_A \)). One can regard \( \rho_A \) as a thermal density matrix of an auxiliary spin chain, which we call a holographic spin chain. The notion of this hidden spin chain was first introduced in Ref. [22]. The entanglement Hamiltonian is defined via \( \rho_A = \exp(\cdot H_E) \).
We can obtain the overlap matrix $M$ analytically for VBS states defined on vertical ladders (i.e. $L_x = 1$) (see Appendix A). For VBS states on lattices with a larger width $L_x (> 1)$, in which case results converge to the 2D limit, we develop an efficient algorithm of MC method (see Appendix B for details). We sample all possible configurations of bosons stochastically, and each matrix element $M_{\alpha \beta}$ can be numerically obtained as the accumulation number of states.

III. ENTANGLEMENT ENTROPY, SPECTRUM, AND NESTED ENTANGLEMENT ENTROPY

In this section, we show the results of entanglement entropy and spectrum for the VBS states obtained by the MC method combined with exact diagonalization. As we will show, the ES of the square (hexagonal) VBS state resembles the energy spectrum of the antiferromagnetic (ferromagnetic) Heisenberg Hamiltonian in one dimension. We also introduce a new quantity, nested entanglement entropy, and further elucidate the relationship between the holographic spin chain and the Hamiltonian for the Heisenberg chain.

A. Entanglement entropy

Let us first study the entanglement entropy (EE) which can be obtained from

$$ S = -\text{Tr}[\hat{\rho}_A \ln \hat{\rho}_A] = -\sum_\alpha p_\alpha \ln p_\alpha, \quad (10) $$

where $p_\alpha$ ($\alpha = 1, 2, \ldots, 2^{L_y}$) are the eigenvalues of $\hat{\rho}_A$. The obtained EE divided by the boundary length for the square and hexagonal lattices are shown in Fig. 2 In both cases, we investigate lattices with both PBC and OBC, results of which are expected to be equivalent in the thermodynamic limit ($L_y \to \infty$). The EE per unit boundary length $S/L_y$ in 2D AKLT model is found to be strictly less than $\ln 2 = 0.693147$, which is in contrast to the result for the 1D AKLT model.\cite{18, 19, 23} Note that the area law is satisfied, as $S/L_y$ approaches to a constant in the thermodynamic limit.

The difference between 1D and 2D EE results can be understood in terms of “valence bond loops” (VBL), which are formed by sequences of singlets connected head-to-tail. (A precise definition of VBL in the context of Schwinger boson can be found in Appendix B) The existence of such loops is a unique feature of 2D VBS states, which provides additional correlations between two separated singlets. As a result, we expect extra correlations between boundary bosons in the 2D VBS states, which lead to modification of the EE from the 1D result. The possibility of forming a valence bond loop decays exponentially fast with respect to its length. (The reason is discussed in Appendix B). This can be related to multiple observed phenomena of EE from our numerical calculation.

First of all, in VBS states on the square lattice, the magnitude of deviation from the 1D result ($S/L_y = \ln 2$) is significantly larger than that of the hexagonal lattice. To understand this, we observe that elemental loops (shortest VBLs that have largest possibility) connects two boundary sites directly in the square lattice, while an extra site is in between two boundary spins in the hexagonal lattice. As a result, the amplitude of elemental loops is higher in the square lattice. In the end, we obtain considerably more VBLs, which then induce larger amount of extra correlations on the boundary in the square lattice than in the hexagonal lattice.

Meanwhile, increasing the number of sites $L_x$ in the bulk direction provides additional valence bond loops which involve sites not only on the boundary, but also inside the two-dimensional lattice. Hence the EE is further reduced when expanding bulk width $L_x$. The effect converges exponentially fast, however. The 2D limit has been almost reached at $L_x = 5$ and $L_x = 3$ for square and hexagonal VBS states, respectively. It is again related to the fact that the amplitude of a VBL decreases with its length.

We also observe that the thermodynamic limit ($L_y \to \infty$) of EE is achieved with totally different behaviors for lattices with rectangular (OBC) and cylindrical (PBC) geometries, as shown in Fig. 2 For VBS states on a lattice with OBC, $S/L_y$ is found to scale with the boundary length $L_y$ as

$$ \frac{S}{L_y} = \sigma + \frac{C_1}{L_y} - \frac{C_2}{L_y \log L_y}, \quad (11) $$

where $C_1, C_2$ ($> 0$) are the fitting parameters and $\sigma$ denotes the EE per boundary length in the thermodynamic limit.
namic limit. The magnitude of $C_2$ is significantly less than $C_1$, as shown in Table I. In contrast, for a lattice wrapped on a cylinder (PBC), the thermodynamic limit is approached exponentially fast in $L_y$, i.e., $\sigma - S/L_y \propto \exp(-L_y/\xi)$, where $\xi$ (also shown in the table) is of the order of the lattice spacing.

|       | OBC          | PBC          |
|-------|--------------|--------------|
| $L_x$ | $C_1$        | $C_2$        |
| 1     | 0.61277(3)   | 0.0865(3)    |
|       | 0.0009(2)    | 0.6129(1)    |
| 2     | 0.59601(4)   | 0.1127(4)    |
|       | 0.0034(3)    | 0.5966(2)    |
| 3     | 0.59322(5)   | 0.1196(5)    |
|       | 0.0049(3)    | 0.5942(3)    |
| 4     | 0.59259(5)   | 0.1223(5)    |
|       | 0.006(3)     | 0.5936(4)    |
| 5     | 0.59246(4)   | 0.1227(5)    |
|       | 0.006(3)     | 0.5934(3)    |

|       | $\sigma$     | $\xi$        |
|-------|--------------|--------------|
| $L_x$ |              |              |
| 1     | 0.0011(7)    | 0.68508(6)   |
| 2     | 0.0012(8)    | 0.684757(4)  |
| 3     | 0.0013(7)    | 0.684754(5)  |

TABLE I: Obtained fitting parameters for entanglement entropy by the method of least squares.

Such distinctively different behaviors of EE for PBC and OBC lattices are closely related to VBL formations. For example, for the square lattice the leading correction to boundary spin correlations and EE is associated with a group of elemental valence bond loops mentioned above, each connecting two nearest neighbor boundary spins. In a lattice with rectangular geometry (OBC), the number of such elemental loops is always 1 less than the number of boundary sites $L_y$. As a result, the leading correction to entropy per boundary spin is proportional to $(L_y - 1)/L_y$, which approaches 1 in the thermodynamic limit. Accordingly, we expect that the entanglement entropy converges slowly following the function $1/L_y$, as observed in Fig. 2.

For a lattice wrapped on a cylinder (PBC), winding loops associated with periodic boundary provide extra spin-spin correlations to the system. The EE in a finite system is lower than the result in the thermodynamic limit, due to the fact that such winding valence bond loops are more prominent in a smaller lattice compared with those in a larger one. Furthermore, amplitudes associated with winding loops decay exponentially fast according to the number of boundary spins $L_y$, which is of the same order of winding loops’ length. As a result, we observe a exponentially converging behavior of the entanglement entropy in a PBC lattice.

### B. Entanglement spectrum

Let us now consider the ES defined as a set of eigenvalues of the entanglement Hamiltonian $H_E := -\ln \rho_A$. In a system with PBC, we are able to study the ES as a function of momentum in the $y$-direction ($k$ in Fig. 3). As shown in Fig. 3 the ES obtained from the square (hexagonal) VBS states resembles the spectrum of the spin-1/2 antiferromagnetic (ferromagnetic) Heisenberg chain. The reason for the dependence of the ES on the lattice structure is as follows: Although both the square and hexagonal lattices are bipartite, neighboring boundary spins belong to the different sublattices in the case of the square VBS state. As a result, the entanglement Hamiltonian is reminiscent of the AFM Heisenberg chain. In contrast, in the hexagonal lattice, all boundary spins belong to the same sublattice, hence the FM spectrum appears. The lowest-lying modes in the left panel can be identified as the des Cloizeaux-Pearson spectrum in the AFM Heisenberg chain. In the right panel, the excitations with the total spin $S = 7$ look like the ordinary spin-wave spectrum in the FM Heisenberg chain. In fact, due to the translational symmetry in the $y$ direction, the Bloch theorem applies and the single-magnon states in the FM chain are exact eigenstates of the RDM for the hexagonal VBS state.

### C. Nested entanglement entropy

In order to further establish the correspondence between the holographic spin chain and the Hamiltonian for the Heisenberg chain, we introduce a measure, which we call nested entanglement entropy (NEE), and study its scaling properties. One might think that the finite-size scaling analysis of the ground state energy $\lambda_0$ is suffi-
The Hamiltonian for the holographic chain low-energy dispersion is given by saturation at about the panel of Fig. 3 (see Table II). The obtained slope shows for a lattice with PBC, where $c$ is the central charge, and $s_1$ is a non-universal constant. In Fig. 4 (a), we show NEE obtained from the square VBS state with $L_x = 5$ and $L_y = 16$. The CFT prediction, Eq. (14), well explains the spatial profile of the NEE. The fit yields $c = 1.01(7)$ which is reasonably close to $c = 1$. The NEE for $\ell = L_y/2$ (half-NEE) is simplified to be $S^{\text{PBC}}(L_y/2, L_y) = (c/3) \ln(L_y) + \text{const}$. From the data with the finite-size scaling form of the NEE, we can also extract the central charge $c$ as summarized in Table III. For the case $L_x = 1$, $c$ is remarkably close to unity. This further supports our conjecture: a correspondence between the entanglement Hamiltonian of the 2D AKLT model and the physical Hamiltonian of the 1D Heisenberg chain. A slight modification of $c$ is observed as the bulk width increases from $L_x = 5$ to $L_x = 5$.

In the case of the rectangular geometry (OBC), a staggered pattern of NEE is expected from studies of the standard EE in open spin chains.

$$S^{\text{OBC}}(\ell, L_y) = \frac{c}{6} \ln(2\ell + 1) + a - \frac{\pi c_1}{2v} \frac{(-1)^\ell}{g(2\ell + 1)^{1/2k}},$$

$$g(\ell) = \frac{2(2\ell + 1)}{\pi} \sin\left(\frac{\pi \ell}{2(L_y + 1)}\right).$$

In Fig. 4 (b), we show the NEE for the square VBS state on the rectangle with $L_x = 5$ and $L_y = 16$. We take the central charge to be $c = 1$ and the Tomonaga-Luttinger parameter $K = 1$, and tune $a$ and $c_1/v$ as fitting parameters. The fit is reasonably good except for the boundaries. This deviation might be due to logarithmic corrections which appear in the SU(2) symmetric AFM spin chains but are not taken into account in Eq. (16).

To provide further evidence for the holographic spin chain, we now consider the hybrid system comprised of squares and hexagons, shown in Fig. 5 (a). It is expected that the entanglement Hamiltonian is described by the FM-AFM alternating Heisenberg model. Figure 5 (b) shows the ES for this system. It is clearly seen that there is a gap between the ground state and the continuum. The gap rapidly saturates with increasing $L_y$. The behavior of the ES is totally consistent with the energy spectrum of the alternating Heisenberg chain whose interactions are denoted $J$ and $J'$. Comparing the bound-state spectrum in Fig. 5 (b) with that of the triplet-pair excitation in the alternating Heisenberg chain, we estimate the ratio of the FM exchange divided by the AFM.
The above expression for $M$ is the Pauli matrix vector. For PBC, $\hat{\Omega}$ 
Schwinger boson representation and coherent state representation. It is convenient to introduce $Z$-matrix defined 

\[
M = \int \left( \prod_{i=1}^{L_y} \frac{(z_i + 1)!}{4\pi} d\Omega_i \right) \frac{1 + \hat{\Omega}_y \cdot \hat{\sigma}_x}{2} \prod_{j=1}^{L_x} \left( \frac{1 - \hat{\Omega}_x \cdot \hat{\Omega}_{y+1}}{2} \right), 
\]

where $z_i$ denotes the coordination number at the $i$-th site, $\hat{\Omega}_i$ is the unit vector defined by $\hat{\Omega}_i := (\sin \theta_i, \cos \phi_i, \sin \phi_i, \cos \theta_i)$, and $\hat{\sigma}_j = (\sigma_j^x, \sigma_j^y, \sigma_j^z)$ is the Pauli matrix vector. For PBC, $\hat{\Omega}_{L_y+1} = \hat{\Omega}_1$. 

The above expression for $M$ can be derived using the Schwinger boson representation and coherent state representation. It is convenient to introduce $Z$-matrix defined 

\[ Z_{xy} = \sum_{\tau} \langle \phi_\tau \rangle \langle \phi_\tau \rangle^\dagger, \]

where $\phi_\tau$ is the coherent state for the $\tau$-th mode.

The authors thank Toshiya Hikihara, Vladimir E. Korepin, Takaumi Suzuki, and Hal Tasaki for valuable discussions, and Hidetoshi Nishimori for TITPACK, ver. 2. This work was supported by Grant-in-Aid for JPSP Fellows (23-7601), for Young Scientists (B) (23740298), for Scientific Research (B) (22340111), and for Scientific Research on Priority Areas (19052004). Numerical calculations were performed on supercomputers at the Institute for Solid State Physics, University of Tokyo.

**Note added**—While completing this work, we became aware of a paper by I. J. Cirac et al.\textsuperscript{22} in which similar results were obtained using different approaches.

**Appendix A: Analytical method for $L_x = 1$**

In this appendix, we show how to explicitly calculate the reduced density matrix for $L_x = 1$ ladders with OBC and PBC based on an extension of the method described in Ref. \textsuperscript{22}, in which the authors analytically obtained entanglement entropies of the VBS states with OBC using a transfer matrix technique. According to Ref. \textsuperscript{22}, the overlap matrix $M$ for vertical ladder, i.e. $L_x = 1$ is given by

\[
M = \int \left( \prod_{i=1}^{L_y} \frac{(z_i + 1)!}{4\pi} d\Omega_i \right) \prod_{j=1}^{L_x} \left( \frac{1 + \hat{\Omega}_y \cdot \hat{\sigma}_x}{2} \right) \prod_{k=1}^{L_y} \left( \frac{1 - \hat{\Omega}_x \cdot \hat{\Omega}_{y+1}}{2} \right), 
\]

where $z_i$ denotes the coordination number at the $i$-th site, $\hat{\Omega}_i$ is the unit vector defined by $\hat{\Omega}_i := (\sin \theta_i, \cos \phi_i, \sin \phi_i, \cos \theta_i)$, and $\hat{\sigma}_j = (\sigma_j^x, \sigma_j^y, \sigma_j^z)$ is the Pauli matrix vector. For PBC, $\hat{\Omega}_{L_y+1} = \hat{\Omega}_1$. 

The above expression for $M$ can be derived using the Schwinger boson representation and coherent state representation. It is convenient to introduce $Z$-matrix defined

\[ Z_{xy} = \sum_{\tau} \langle \phi_\tau \rangle \langle \phi_\tau \rangle^\dagger, \]

where $\phi_\tau$ is the coherent state for the $\tau$-th mode.

The authors thank Toshiya Hikihara, Vladimir E. Korepin, Takaumi Suzuki, and Hal Tasaki for valuable discussions, and Hidetoshi Nishimori for TITPACK, ver. 2. Numerical calculations were performed on supercomputers at the Institute for Solid State Physics, University of Tokyo.

**Note added**—While completing this work, we became aware of a paper by I. J. Cirac et al.\textsuperscript{22} in which similar results were obtained using different approaches.

**Appendix A: Analytical method for $L_x = 1$**

In this appendix, we show how to explicitly calculate the reduced density matrix for $L_x = 1$ ladders with OBC and PBC based on an extension of the method described in Ref. \textsuperscript{22}, in which the authors analytically obtained entanglement entropies of the VBS states with OBC using a transfer matrix technique. According to Ref. \textsuperscript{22}, the overlap matrix $M$ for vertical ladder, i.e. $L_x = 1$ is given by

\[
M = \int \left( \prod_{i=1}^{L_y} \frac{(z_i + 1)!}{4\pi} d\Omega_i \right) \prod_{j=1}^{L_x} \left( \frac{1 + \hat{\Omega}_y \cdot \hat{\sigma}_x}{2} \right) \prod_{k=1}^{L_y} \left( \frac{1 - \hat{\Omega}_x \cdot \hat{\Omega}_{y+1}}{2} \right), 
\]

where $z_i$ denotes the coordination number at the $i$-th site, $\hat{\Omega}_i$ is the unit vector defined by $\hat{\Omega}_i := (\sin \theta_i, \cos \phi_i, \sin \phi_i, \cos \theta_i)$, and $\hat{\sigma}_j = (\sigma_j^x, \sigma_j^y, \sigma_j^z)$ is the Pauli matrix vector. For PBC, $\hat{\Omega}_{L_y+1} = \hat{\Omega}_1$. 

The above expression for $M$ can be derived using the Schwinger boson representation and coherent state representation. It is convenient to introduce $Z$-matrix defined

\[ Z_{xy} = \sum_{\tau} \langle \phi_\tau \rangle \langle \phi_\tau \rangle^\dagger, \]

where $\phi_\tau$ is the coherent state for the $\tau$-th mode.
by

\[ Z(L_y; \{ \sigma_i \}) := \int \left( \prod_{i=1}^{L_y} \frac{d\Omega_i}{4\pi} \right) \prod_{j=1}^{L_y} (1 + \Omega_j \cdot \sigma_j) \]
\[ \times \prod_{k=1}^{L_y} (1 - \Omega_k \cdot \Omega_{k+1}), \quad (A2) \]

Since the only difference between \( M \) and \( Z \) is the overall factor, the spectrum of \( \hat{\rho}_A \) is equivalent to that of the following matrix:

\[ \rho'_A := \frac{Z(L_y; \{ \sigma_i \})^2}{\text{Tr} \left[ Z(L_y; \{ \sigma_i \})^2 \right]}, \quad (A3) \]

where \( \text{Tr} \) is taken over \( \sigma \)-spin spaces. Then in order to calculate entanglement properties of the VBS state on a vertical ladder, it is necessary to obtain the explicit form of \( Z \)-matrix. There is a useful relation shown in lemma 3.3 in Ref. [14]:

\[ \int \frac{d\Omega_i}{4\pi} (\sigma_i \cdot \Omega_i)(\sigma_i \cdot \sigma_j) = q\sigma_i \cdot \sigma_j, \quad (A4) \]

where \( q = 1/3 \). Using the above relation we obtain the following relation:

\[ Z(L_y; \{ \sigma_i \}) = \sum_{\{i_1, \ldots, i_{2n}\}} q^n (-q)^{i_1} \cdots (-q)^{i_n} \]
\[ \times (\sigma_{i_1} \cdot \sigma_{i_2}) \cdots (\sigma_{i_{2n-1}} \cdot \sigma_{i_{2n}}), \quad (A5) \]

where \( l_j = \text{mod}(i_{2j} - i_{2j-1}, L_y) \) and \( 1 \leq i_1 < i_2 < \cdots < i_{2n-1} \leq L_y \). The summation is taken over admissible combinations of \( \{i_j\}_{j=1}^{2n} \) for \( 0 \leq n \leq N/2 \). It is useful to express Eq. (A5) in terms of graphical representations.

Figure 6 shows the relationship between the original VBS state and the one-dimensional holographic spin chain. The circles in the right panel in Fig. 6 indicate the sites in the spin chain, on which the Pauli vectors \( \{ \sigma_i \} \) in Eq. (A3) act. \( Z \)-matrix is represented by sum of admissible configurations each of which has a corresponding graph (see Fig. 6). Here the number of admissible configurations is \( 2^{L_y} \).

Let us consider the \( L_y = 4 \) case for illustrative purposes. Figure 7(a) shows all admissible configurations for OBC using a bit representation in which the thin and thick lines denote 0 and 1, respectively. The end points of thick lines in Fig. 7 indicate \( \{ i_1 \} \). For example, the contributions of the states 3 and 5 to the \( Z \)-matrix are expressed as

\[ q^3(-q)^2 (\sigma_1 \cdot \sigma_3), \quad (A6) \]
\[ q^2(-q)^4 (\sigma_1 \cdot \sigma_2)(\sigma_3 \cdot \sigma_4), \quad (A7) \]

respectively. Note that \( n \) in Eq. (A3) corresponds to the number of clusters connected by thick lines contiguously in each graphical representation. Summing all contributions, we arrive at the following expression for the \( Z \)-matrix:

\[ Z^{\text{OBC}}(4; \{ \sigma_i \}) = I - q^4[(\sigma_1 \cdot \sigma_2) + (\sigma_2 \cdot \sigma_3) + (\sigma_3 \cdot \sigma_4)] \]
\[ + q^3[(\sigma_1 \cdot \sigma_3) + (\sigma_2 \cdot \sigma_4)] \]
\[ + q^2[(\sigma_1 \cdot \sigma_2)(\sigma_3 \cdot \sigma_4) - (\sigma_1 \cdot \sigma_4)], \quad (A8) \]

where \( I \) is a \( 2^{L_y} \)-dimensional identity matrix.

Next, we examine the case of PBC where the number of admissible configurations is \( 2^{L_y}(=2^{L_y}) \). We have to consider the states depicted in Fig. 7(b) in addition to the states in Fig. 7(a). For example, contribution of the state 11 to the \( Z \)-matrix is given as

\[ q^3(-q)^3 (\sigma_4 \cdot \sigma_3). \quad (A9) \]

Including additional contributions from the states from 8 to 15 in Fig. 7(b), the \( Z \)-matrix for PBC is given as

\[ Z^{\text{PBC}}(4; \{ \sigma_i \}) = Z^{\text{OBC}}(4; \{ \sigma_i \}) - q^2(\sigma_4 \cdot \sigma_1) \]
\[ + q^3[(\sigma_1 \cdot \sigma_2) + (\sigma_3 \cdot \sigma_1) + I] \]
\[ + q^4[(\sigma_1 \cdot \sigma_1)(\sigma_2 \cdot \sigma_3) - (\sigma_1 \cdot \sigma_3) \]
\[ - (\sigma_3 \cdot \sigma_2) - (\sigma_2 \cdot \sigma_1)]. \quad (A10) \]

In principle, we can obtain an explicit form of the \( Z \)-matrix for larger \( L_y \) using the method based on the graphical representations.

Next we show how to calculate the \( Z \)-matrices for hexagonal-lattice vertical ladders (i.e. \( L_x = 1 \)). The relationship between the VBS on the hexagonal-lattice vertical ladder and the holographic spin chain is shown in Fig. 8. The only difference between the square and hexagonal vertical ladders is the definition of the length between sites on the holographic spin chain. We can then calculate the \( Z \)-matrix for the hexagonal-lattice vertical ladder as follows:

\[ Z(L_y; \{ \sigma_i \}) = \sum_{\{i_1, \ldots, i_{2n}\}} q^n(-q)^{2l_1} \cdots (-q)^{2l_n} \]
\[ \times (\sigma_{i_1} \cdot \sigma_{i_2}) \cdots (\sigma_{i_{2n-1}} \cdot \sigma_{i_{2n}}), \quad (A11) \]
where $l_j = \text{mod}(i_2j - i_2j-1, L_y)$ and $1 \leq i_1 < i_2 < \cdots < i_{2n-1} \leq L_y$. The difference between Eq. (A10) and Eq. (A11) is an exponent of $(-q)$.

After we obtain an explicit form of $Z$-matrix, we can study entanglement properties. Indeed, we have compared the results based on this method with those obtained by Monte Carlo method and have confirmed that they are completely consistent, which ensures the validity of our Monte Carlo approach.

**Appendix B: Monte Carlo Method for Calculating Overlap Matrix**

In this appendix, we explain our proposed Monte Carlo method used for obtaining the overlap matrix $M$. As we mentioned in Sec. II, the VBS state can be regarded as a singlet-covering state, expressed by Eq. $\text{(2)}$. In the case of bipartite lattices (square and hexagonal), we can avoid negative signs by a local gauge transformation:

$$
|\Psi\rangle = \prod_{\langle i,j \rangle} (c_i^{(1)}|c_j^{(1)}\rangle + c_i^{(2)}|c_j^{(2)}\rangle)|\text{vac}\rangle,
$$

where $\langle i,j \rangle$ runs over all connected neighboring sites in the graph. If we introduce $\tau = 1, 2$ as the quantum number of SU(2) boson operators, the VBS state can be written as

$$
|\Psi\rangle = \sum_{\{\tau_{jk}\} \in \Omega} \left( \prod_{\langle i,j \rangle} c_i^{(\tau_{ij})} \right) \left( \prod_{\langle j,k \rangle \in \Omega} c_j^{(\tau_{jk})} \right) \left| \text{vac} \right. ,
$$

where $\tau_{jk}$ denotes the boson between $j$-th and $k$-th site on the bulk of the subsystem $\Omega$. As a result, we can reproduce VBS state through stochastic sampling of boson configurations $\{\tau_{jk}\}$ of the system.

The element of overlap matrix $M$, is given by

$$
M_{\{\sigma_i\}, \{\sigma_j\}} = \langle \{\sigma_i\} | \{\sigma_j\} \rangle ,
$$

where $\{|\sigma_i\rangle\}$ is the VBS state with fixed boundary $\{\sigma_i\}$:

$$
|\{\sigma_i\}\rangle = \sum_{\{\tau_{jk}\} \in \partial \Omega} \left( \prod_{\langle i,j \rangle \in \Omega} c_i^{(\tau_{ij})} \right) \left( \prod_{\langle j,k \rangle \in \partial \Omega} c_j^{(\tau_{jk})} \right) \left| \text{vac} \right. ,
$$

where $\partial \Omega$ denotes the boundary of $\Omega$. The variables $\{\sigma_i\}, i \in \partial \Omega$ specifies the unpaired spins on the boundary. We can further simplify the problem by considering (B5) in the occupation number basis:

$$
|\{\sigma_i\}\rangle = \sum_{\{\tau_{jk}\}} w(\{n_j^{(\alpha)}\})|\{n_j^{(\alpha)}\}\rangle ,
$$

where $n_j^{(\alpha)} = \sum_{k \in \delta j} \delta(\tau_{jk}, \alpha)$ (the summation is taken over all nearest neighbor sites of $j$) is the number of bosons of type $\alpha$ at the site $j$. The degeneracy of occupation number state can be easily derived as:

$$
w(\{n_j^{(\alpha)}\}) = \prod_{j \in \Omega} \sqrt{n_j^{(1)}n_j^{(2)}} .
$$

As a result, we obtain the element of the overlap matrix
as

$$M(\sigma' \{\sigma_i\}; \{\tau_{jk}\}) = \sum_{\{\tau'_{jk}\}; \{\tau_{jk}\}} W(\{n_j^{(\tau_{jk})}\}) \delta(\{n_j^{(\tau'_{jk})}\}, \{n_j^{(\tau_{jk})}\}),$$

(B8)

with weight

$$W(\{n_j^{(\tau_{jk})}\}) = w^2(n_j^{(\tau_{jk})}) = \prod_{j \in \Omega} (n_j^{(1)})!n_j^{(2)}!(1).$$

(B9)

In the end, by generating boson states $\Sigma = \{(\tau'_{jk}), \{\tau_{jk}\}\}$ stochastically while keeping the constraint $n_j^{(\tau')} = n_j^{(\tau)}$ for all $j$ and $\tau$, we can numerically calculate the element of the overlap matrix $M(\sigma' \{\sigma_i\}; \{\sigma_i\})$ as accumulation number of boson configurations with corresponding boundary condition, through Monte Carlo importance sampling. It is convenient to introduce graphical representation for each boson configurations $\{(\sigma_i), \{\tau_{jk}\}\}$, as shown in Fig. 9. The red (dark) and blue (light) lines indicate bosons with quantum number $\tau_{jk} = 1$ and 2, respectively. Colored but unconnected dots on the edge correspond to boundary bosons $\{\sigma_i\}$. Notice that we show two layers in the graphical representation, as they stand for the sub-system state $|\Psi^{(A)}\rangle$ and its conjugate $\langle \Psi^{(A)}|$, respectively. Due to the fact that the full system is reflection symmetric, one may also consider two layers as two subsystems $A$ and $B$, with sites (big circles) and bonds (lines) on top of each other being symmetric counterparts.

Using this graphical representation, we can easily illustrate two MC update schemes we use to sample all possible boson configurations, while automatically satisfying the constrain: $n_j^{(\tau)} = n_j^{(\tau')}$ for all $j$ and $\tau$.

(i) Inter-layer flip (Left panel of Fig. 9): In the boson state $\Sigma$, we choose arbitrarily a valence bond connecting sites $j$ and $k$ such that $\tau_{jk} = \tau'_{jk} = \mu$ (colored as red/blue) is satisfied. A trial state $\Sigma_t$ is given as $\tau_{jk} = \tau'_{jk} = 3 - \mu$ (colored as blue/red) with all other bosons unchanged. The update is accepted/rejected according to the ratio of probabilities $W(\Sigma_t)/W(\Sigma)$ which satisfies detailed-balance condition. In Fig. 9, a yellow loop is drawn showing bosons being flipped ($\tau_{jk} = \mu \rightarrow 3 - \mu$).

(ii) Intra-layer flip (Right panel of Fig. 9): In order to apply intra-layer flip without violating the constraints, we attempt to construct a “valence bond loop” (VBL), or a sequence of connected singlets, with alternating colors ($\tau_{jk} = 1 \leftrightarrow 2$). Flipping a VBL is equivalent to operating on the VBS state (except for the weight change), where the loop is formed by $l$ sites $\{i_k\}$ in the order of $\kappa = 1, 2, ..., l$, and $\mu, \nu$ are the alternating colors along the loop. (from red to blue and vice versa). In the right column of Fig. 9, we show a possible loop that consists of 4 sites and 4 valence bonds, denoted by yellow region. In our MC simulation scheme, we construct a loop by using a random walker. The walker starts from a randomly chosen site, as well as a randomly chosen direction. After such a movement, we choose next direction so that the color of next valence bond alternates. Since turning back to the previous site is in the list of candidates, it is always possible to choose such a direction. When the walker comes back to the initial position, the loop is formed. Therefore, loops can be of arbitrary length, as long as color is alternating along the loop. Meanwhile, the possibility (amplitude) decrease significantly for longer loops. Nevertheless, obviously, flipping all the bonds in a valence bond loop does not affect the occupation number $n_j^{(\alpha)}$ at any site on the loop.

Following above two updating rules, we can obtain efficiently the overlap matrix with high accuracy, while satisfying the ergodicity condition. This MC sampling approach can be applied to arbitrarily large systems. Number of sites along the bulk dimension has limited effect on the cost of calculations. The computational limit is mainly related to the diagonalization of the overlap matrix, the dimension of which grows exponentially as the number of boundary sites increases.
