In this work casein (CN) was used as a carrier system for the hydrophobic agent α-tocopherol (α-TOC), and an amphiphilic self-assembling micellar nanostructure was formed with ultrasound treatment. The interaction mechanism was detected with UV-Vis spectroscopy, fluorescence spectroscopy, proton spectra, and Fourier transform infrared spectroscopy (FTIR). The stability of the nanoparticles was investigated by using typical processing and storage conditions (thermal, photo, 20 ± 2 °C and 4 ± 2 °C). Oil-in-water emulsions containing the self-assembled nanoparticles and grape seed oil were prepared, and the effect of emulsion oxidation stability was studied using the accelerated Rancimat method. The results indicated that the UV-Vis spectra of α-TOC/CN nanoparticles complexes were different for ultrasonic treatments performed with different combinations of power (100, 200, 300 W) and time (5, 10, and 15 min). The results of UV-Vis fluorescence spectrum data indicated that the secondary structure of casein changed in the presence of α-TOC. The nanoparticles exhibited the chemical shifts of conjugated double bonds. Interactions between α-TOC and casein at different molar concentrations resulted in a quenching of the intrinsic fluorescence at 280 nm and 295 nm. Moreover, by performing FTIR deconvolution analysis and multicomponent peak modeling, the relative quantitative amounts of α-helix and β-sheet protein secondary structures were determined. The self-assembled nanoparticles can improve the stability of α-TOC by protecting them against degradation caused by light and oxygen. The antioxidant activity of the nanoparticles was stronger than those of the two free samples. Lipid hydroperoxides remained at a low level throughout the course of the study in emulsions containing 200 mg α-TOC/kg oil with the nanoparticles. The presence of 100 and 200 mg α-TOC/kg oil led to a 78.54 and 63.54 μmol/L inhibition of TBARS formation with the nanoparticles, respectively, vs the free samples containing control after 180 mins.

1. Introduction

Vitamin E is a fat-soluble vitamin composed of eight different forms of tocopherols (α, β, γ, and δ) and tocotrienols (α, β, γ, and δ) [19]. Vitamin E compounds are known to inhibit lipid oxidation in foods, and the most biologically active of these compounds is α-TOC [31,33]. Therefore, it has been used as a food additive [6]. α-TOC is known to protect polyunsaturated lipids by binding and trapping free radicals and by quenching singlet molecular oxygen [24].

The lipophilic compound α-TOC is poorly soluble in water and biologically unstable against factors such as light and oxygen. This limits its storage and applications in the pharmaceutical, food, and cosmetic industries [20,30]. The existing delivery systems have been designed to improve the performance of α-TOC with the advantages of low dose frequency and superior bioactivity and stability, for example, in microencapsulation [41], liposomes [29] and as nanoparticles [13]. Multiple methods for encapsulating α-TOC in polymeric nanoparticles have been reported, but studies and applications related to the preparation of α-tocopherol/casein nanoparticles by using ultrasound have not been reported thus far. Moreover, details pertaining to the strength and mechanism of the interaction between casein and α-TOC by ultrasonic treatment have not been revealed yet. Thus, the objective of the present study is to determine the ultrasound conditions required to produce more stable α-tocopherol/casein nanoparticles.

Casein is an amphiphilic self-assembling protein, and it offers certain advantages as a natural vehicle for bioactive compounds [3]. The...
structural and physicochemical properties of casein, have been described, such as the binding of ions and small molecules and excellent emulsification and self-assembly properties [8,26,32,42]. Furthermore, casein reportedly interacts with bioactive compounds, such as blueberry anthocyanins [45] and vitamin A [32]. These reports explore the effects of carriers on bioactive compounds under various processing conditions and their interaction mechanism. The protective effects of casein on the stability and antioxidant capacity of α-TOC and their interaction mechanism are reported in this study. Fourier deconvolution analysis and Gaussian curve fitting are employed to provide detailed information on the structure of casein after ultrasonic treatment.

In contrast to previous reports about nanoparticles, the present study attempts to evaluate the influences of different ultrasound powers and ultrasonic times on the particle size, polydispersity index, and protein structure of the encapsulated nanoparticles loaded with α-TOC. The protective effects of casein on the stability and antioxidant capacity of α-TOC are examined. The strength and mechanism of interaction between casein and α-TOC are elucidated using different spectroscopic methods and proton spectra. Moreover, the antioxidant ability is employed to produce a grape seed oil emulsion by using the lipid hydroperoxides (LOOH) and thiobarbituric acid reactive substances (TBARS) assays.

2. Materials and methods

2.1. Materials

Casein sodium salt, α-TOC (purity of 96%), and 1, 1, 3, 3-tetraethoxyxyp propane were purchased from Sigma–Aldrich Chemical Co. (St. Louis, MO, USA). Cumene hydroperoxide was purchased from Sigma–Aldrich Chemical Co. (St. Louis, MO, USA). All other chemicals of analytical grade were purchased from Sinopharm Chemical Reagent Co. Ltd. (Shanghai, China). Ultrapure water was utilized throughout.

2.2. Methods

2.2.1. Sample preparation

Self-assembled casein nanoparticles containing α-TOC were prepared as described by Semo et al. [7]. The α-TOC solution was prepared as follows: 0.01, 0.007, and 0.005 g of α-TOC were dissolved separately in 10 mL of anhydrous ethanol, and the resulting solutions were oscillated for 2 min. After the complete dissolution of α-TOC, the solutions were stored in a refrigerator (4 ± 2°C). Casein was dissolved in distilled water at a concentration of 2 mg/mL. The pH was adjusted to about 10 by using 0.1 mol/L NaOH. This system was stirred at room temperature for 3 h and then stored in a refrigerator (4 ± 2°C) for 8 h. Thereafter, the system pH was adjusted to about 6.8 by using 0.1 mol/L HCl. Then, α-TOC was added to the system in different mass ratios (Table 1), and the resulting samples were treated in an ultrasonic cell crus her (on 2 s, off 3 s, ω 20 mm, XO1200D, China) with different combinations of power (100, 200, 300 W) and treatment duration (5, 10, and 15 min). Approximately 4 mL of 1 mol/L tripotassium citrate, 24 mL of 0.2 mol/L K3HPO4, and 20 mL of 0.2 mol/L CaCl2 were added. Thereafter, four consecutive additions of 2.5 mL of 0.2 mol/L K2HPO4 and 5 mL of 0.2 mol/L CaCl2 were performed at 15-min intervals. During this process, the samples were stirred with a magnetic stirrer, sample temperature was maintained at 37°C, and sample pH was adjusted between 6.8 and 7.0 by using either 0.1 mol/L HCl or 0.1 mol/L NaOH. The final dispersions were stirred at 350 rpm/min for 1 h. The samples were then treated for 20 s at 74°C in a water bath. The control sample was prepared by following the same procedure.

2.2.2. Preparation of grape seed oil emulsion

A grape seed oil emulsion was prepared following the method described by Shao & Tang [44]. Oil-in-water emulsions containing grape seed oil (30%, w/w) in the oil phase were produced using a high-speed blender (Fluko, Shanghai, China) operated at 10,000 rpm for 3 min. The oil droplet size was further reduced using a high-pressure homogenizer (Ah-Basic, ATS) operated at 50 MPa. Nanoparticles prepared with a mass ratio of 1:200 were added to the emulsions. The ultrasound treatment power was 300 W, and the duration was 5 min, respectively. The net α-TOC contents were 100 mg/kg and 200 mg/kg, respectively. The mixtures were then homogenized twice at 50 MPa by using a high-pressure homogenizer (Ah-Basic, ATS) to improve nanoparticle distribution in the interfacial regions.

Approximately 3 mL of the emulsions were placed in a professional rancimat (Metrohm, 892, Swiss) and removed at 30-min intervals between 0 and 3 h. Accelerated oxidation conditions were employed. The heater temperature and gas flow rate were set to 60°C and 20 L/h, respectively. The emulsions were prepared in duplicate for the LOOH and TBARS assays.

2.3. Experimental design

An orthogonal rotation combination test design comprising three levels and four factors, namely ultrasonic treatment power, ultrasonic treatment time, mass ratio, and control, was used to optimize the model and reaction conditions (Table 1). Encapsulation efficiency was set as the index of this ultrasound process.

Encapsulation efficiency was determined following a modified version of a procedure described in the literature [19]. Encapsulation efficiency was defined as the difference between the total α-TOC content used during preparation and the free α-TOC content obtained after separation from the medium. Briefly, the suspensions were accurately injected into a centrifugal ultrafiltration device. Filtrates were extracted from the suspensions by means of centrifugation at 4000 rpm for 30 min. Hexane was added to the α-TOC extracted from the filtrate and the resulting mixture was subjected to vortexing. The free α-TOC concentration was assayed using a UV–Vis spectrophotometer (Agilent, Cary 60, Malaysia) at 297 nm. The encapsulation efficiency (EE, %) was calculated using equation (1):

$$EE(\%) = \frac{W_f - W_r}{W_f} \times 100$$

where $W_f$ is the total amount of α-TOC used during the preparation, and $W_r$ is the amount of free α-TOC in the filtrate.

2.4. UV–Vis spectroscopy and calibration curve

The self-assembled casein nanoparticles were dissolved in phosphate buffer solution (PBS, pH = 7.0) with the final concentration of 0.15 mg/mL. UV–Vis spectra of the solution were recorded with a UV–Vis spectrophotometer (Agilent, Cary 60, Malaysia) scanning from 190 to 400 nm at room temperature. The scan resolution was 0.5 nm, scanning step was 1 nm, and scanning rate was 50 nm/min. PBS was used as a blank control [24,27].

A absorbance vs concentration calibration curve was plotted for different concentrations of α-TOC dissolved in hexane. Initially, 200 mg of α-TOC was accurately weighed, and the volume was eventually

Table 1

| Column | Factor | Ultrasonic time/min | Ultrasonic power/W | Mass ratio | Control |
|--------|--------|----------------------|-------------------|------------|---------|
| 1      | 1      | 5                    | 100               | 1:200      | 1       |
| 2      | 2      | 5                    | 200               | 1:300      | 2       |
| 3      | 3      | 5                    | 300               | 1:400      | 3       |
| 4      | 4      | 10                   | 100               | 1:300      | 3       |
| 5      | 5      | 10                   | 200               | 1:400      | 1       |
| 6      | 6      | 15                   | 200               | 1:400      | 2       |
| 7      | 7      | 15                   | 300               | 1:400      | 2       |
| 8      | 8      | 20                   | 200               | 1:200      | 3       |
| 9      | 9      | 30                   | 300               | 1:300      | 1       |
increased to 100 mL by adding hexane. Then, 1 mL of the solution was placed in a 10-mL volumetric flask, and the volume of this solution was eventually increased to 10 mL by adding hexane; the resulting solution was called the working solution. Approximately 0.5, 1.0, 1.5, 2.0, and 2.5 mL of the working solution were accurately weighed and eventually diluted to 10 mL by using hexane. The absorbance of the diluted samples was assayed using a UV–Vis spectrophotometer (Agilent, Cary 60, Malaysia) at 297 nm. A hexane sample was used as the blank control. The standard curve was plotted with the mass concentration of α-TOC as the abscissa and its absorbance as the ordinate. The following one-dimensional linear regression equation was obtained: \[ y = 15.737x + 0.0252, R^2 = 0.9963 \]

2.5. Proton spectra

Nuclear magnetic resonance (NMR) spectra were recorded using a Bruker Avance III HD instrument. 1H NMR spectra were obtained with a spectral width of 500 MHz, acquisition time of 3.9 s, delay of 2 s, and pulse angle of 45°. The proton spectrum analysis was performed with a total of 16 scans.

2.6. Size determination

The particle size and PDI of the α-TOC/CN nanoparticles were measured after the resuspension of lyophilized nanoparticles by using the modified method reported by Zigoneau et al. [13]. The particle size and PDI of both casein and α-TOC/CN nanoparticles were determined with dynamic light scattering (Nano ZS, Malvern, UK) by using a He/Ne laser (\( \lambda = 632.8 \) nm). Particle size analysis of the emulsion droplets was performed at 25°C by following a previously described procedure [39]. All measurements were repeated thrice.

2.7. Fluorescence spectroscopy

The molar concentration ratio of α-TOC to casein was set variously to 3:1, 4:1, and 5:1. Fluorescence spectroscopy was performed using a spectrophotofluorometer (Gangdong, F-280, China) scanning from 250 to 380 nm at the excitation wavelengths of 280 nm and 295 nm. The excitation and emission bandwidths were 10 nm, and the scan speed was 60 nm/min; PBS was used as the blank control [2,47].

2.8. Fourier transform infrared spectroscopy

Fourier transform infrared (FTIR) analysis was performed using a Fourier transform infrared spectrometer (Shimadzu, IR Affinity-1, Japan) scanning from 4,000 to 400 cm\(^{-1}\) at room temperature. KBr was pressed into plates and solution samples were dripped onto these plates for measurement. The analysis was performed with a total of 32 scans at the resolution of 4 cm\(^{-1}\).

2.9. Stability testing

To investigate nanoparticle stability, stability tests were conducted under modified versions of four conditions described in the literature [19,29,45]. A photo stability test was conducted by exposing the samples to an illumination intensity of 15 W for 180 min. A thermal treatment stability test was conducted by heating the samples in an air dry oven at 50 °C for 6 h. Storage stability tests were conducted for 6 d at room temperature (20 ± 2 °C) and in a refrigerator (4 ± 2 °C). The stability of the self-assembled casein nanoparticles was compared with that of the free α-TOC.

The retention rate was presented as the remaining absorbance with time of exposure. The nanoparticle samples treated under the four aforementioned conditions were mixed with anhydrous ethanol in equal volume with stirring, and 200 μL of 1 mol/L NaOH was added into the mixtures. α-TOC was extracted from the emulsions by using hexane until the water phase was colorless and transparent, and the free α-TOC concentration was assayed using a UV–Vis spectrophotometer (Agilent, Cary 60, Malaysia) at 297 nm.

2.10. Antioxidant activity testing

LOOH was determined according to a previously described procedure [37]. A sample (0.3 mL) was mixed in a glass tube with 1.5 mL isooctyl alcohol-isopropanol (3:1, v/v) on a vortex mixer for 10 s and centrifuged at 4,000 rpm for 10 min to separate the phases. A 200-μL sample of the resulting supernatant (organic phase) was mixed thoroughly with 2.8 mL of methanol-buty alcohol (2:1, v/v). Ammonium thiocyanate solution (50 μL, 3.94 mol/L) was added to the resulting mixture. Then, 50 μL of iron (II) solution was added, and the resulting mixture was mixed using a vortex mixer for 5 s. After incubation for 20 min at room temperature with appropriate stirring, the absorbance of the sample was determined at 510 nm against a blank that contained all of the reagents except for the sample by using a UV–Vis spectrophotometer (Agilent, Cary 60, Malaysia). LOOH concentrations were determined from a standard curve prepared using cumene hydroperoxide.

The secondary oxidation products were monitored with the thio-barbituric acid reactive substances (TBARS) method by following a procedure described elsewhere [37,48]. Approximately 2 mL of each sample was mixed with 4 mL of TBA reagent containing 15% w/v trichloracetic acid and 0.375% w/v thio-barbituric acid in 0.25 mol/L HCl in screw-capped tubes and placed in a boiling water bath for 15 min. The samples were then cooled to room temperature and centrifuged at 1,600 g for 20 min. The absorbance of the supernatant was measured at 532 nm by using a UV–Vis spectrophotometer (Agilent, Cary 60, Malaysia). The TBARS concentrations were determined from a standard curve prepared using 1,1,3,3-tetraethoxypropane.

2.11. Statistical analysis

The experimental data were statistically analyzed and expressed using SPSS20.0 (IBM Corp., Armonk, NY, USA). All diagrams were plotted using Origin 8.1 software (Microcal, USA). The significance correlations were defined as (p < 0.05) and (p < 0.01).

3. Results and discussion

3.1. UV–Vis spectra of casein after binding with α-TOC

The interaction of small molecules with protein was investigated by means of UV–Vis spectroscopy to confirm the structural changes that occurred in the protein during ultrasonic treatment. Changes in the peak wavelength and absorption spectral intensity of the small molecules with protein represent the strength and mechanism of the interaction.

The UV–Vis spectra of α-TOC/CN nanoparticles exhibited significant changes (Fig. 1). Two distinct characteristic absorption peaks were observed in the wavelength ranges of 195.5–212 nm and 275.5–285.5 nm. The former wavelength range was mainly characterized by changes in peptide bonds, that is, the α-helix structure of protein, while the latter wavelength range was mainly characterized by the absorption peaks of chromogenic groups such as tryptophan and tyrosine [34]. The absorbance intensities of α-TOC/CN nanoparticles were different during intensity measurements in the case of all of the ultrasonic treatments investigated herein (Fig. 1). A possible reason is that the hydrophobic groups in denatured proteins were exposed upon ultrasonic treatment [11,35], resulting in increased fluorescence intensity. Fig. 1 shows that the maximum absorption wavelength (195.5–212 nm) of the system increased with the addition of α-TOC, which led to the formation of α-TOC/CN. These results agreed with those of Tang et al. [22], who reported that the absorption wavelength of C3G-BSA increased with the addition of C3G. The secondary structure of casein was affected by the
newly formed compound [22]. As reported by Hu et al. [11] and Zhang et al. [35], the functional properties of protein can be modified with ultrasound treatment, which induces several secondary structural changes as well. These effects of ultrasound are consistent with the results reported in the literature, wherein the mechanism of ultrasound was confirmed [10,11,16,35].

The untreated samples formed more elastic and compact dispersions, while the ultrasonic-treated samples formed more viscous and loosened dispersions. This is because as the ultrasonic treatment time and power increase, as a protein denatured, more hydrophobic groups are exposed due to the instantaneous extreme temperatures and pressures generated by ultrasound [14,35]. Moreover, the results indicated that the optimum orthogonal array design analysis conditions were as follows: Ultrasonic power $= 300$ W, ultrasonic treatment time $= 5$ min, and mass ratio $= 1:200$. The nanoparticles prepared using the optimized conditions exhibited an encapsulation efficiency of 97.29 ± 5.2%. These results suggest that there is a balance between the aggregation and exposure of hydrophobic groups [4], resulting in the formation of self-assembled nanoparticles with a hydrophobic core, which could be ideal nano-scale carriers for lipophilic drugs [3,23].

3.2. Proton spectra

The two purified products ($\alpha$-TOC and casein) and $\alpha$-TOC/CN nanoparticles were characterized with $^1$H NMR. The chemical shifts were read and are presented in Fig. 2. Compared to the free samples, the nanoparticles exhibit the chemical shifts of conjugated double bonds, as can be observed from their spectrum. A combined analysis of UV, Fluorescence spectra and NMR data confirmed the binding of casein to $\alpha$-TOC.

3.3. Size determination

As summarized in Table 2, the average diameters of the casein particles were 198.40 ± 0.56 nm and 170.93 ± 1.86 nm with and without ultrasound treatment, respectively. The average PDI of the $\alpha$-TOC/CN nanoparticles (under optimum conditions) was 0.24 ± 0.02, which was slightly smaller. Madadlou et al. [5] observed similar results for casein micelles, which indicates that the homogeneity of the particles increased owing to sonication. Nanoparticles were added into the formed emulsions post-treatment by using a high-pressure homogenizer. The emulsions produced with the net $\alpha$-TOC content of 100 mg/kg had a mean droplet size of 296.07 ± 15.14 nm, whereas the emulsions produced with the net $\alpha$-TOC content of 200 mg/kg had a smaller mean droplet size of 251.43 ± 16.97 nm. A possible reason was that the mean droplet size decreased as the amount of casein added increased [39].

3.4. Fluorescence spectra of casein after binding with $\alpha$-TOC

Information about the binding properties of small molecules to protein, such as the binding mechanism, binding model, binding constant, and binding sites, can be gleaned from their fluorescence spectra [46]. The fluorescence spectra of nanoparticles recorded at 280 nm and 295 nm in the presence of different molar concentrations of $\alpha$-TOC are shown in Fig. 3.

The fluorescence intensity of a protein can mainly be ascribed to the Trp, Tyr, and Phe residues [9,23]. According to Fig. 3, the fluorescence intensity of casein decreases regularly with a gradual increase in the

| Change of particle size and PDI of casein solution as a result of sonication. |
|-----------------|-----------------|
| particle size (nm) | PDI |
| Casein (without ultrasound treatment) | 198.40 ± 0.56 | 0.40 ± 0.01 |
| $\alpha$-Tocopherol/casein nanoparticles (with ultrasound treatment) | 170.93 ± 1.86 | 0.24 ± 0.02 |

Fig. 2. $^1$H NMR spectrum of samples. (a) $\alpha$-TOC/CN nanoparticles without ultrasound, (b) $\alpha$-TOC/CN nanoparticles with ultrasound, (c) casein, (d) $\alpha$-TOC.
α-TOC concentration, indicating that the interaction between casein and α-TOC occurred, and α-TOC/CN complexes were formed. Liang, Tremblay-Hebert, & Subirade [21] reported that binding of α-tocopherol to β-lg which reduced the turbidity and improved the solubility of fat-soluble vitamins and that the fluorescence intensity decreased with the addition of α-tocopherol. In addition, when the excitation wavelength was 280 nm (Fig. 3A), the maximum emission wavelength of casein exhibited a red shift, which indicated that the chromophore of casein was placed in a more hydrophobic environment upon the addition of α-TOC. Changes to the protein structure were more remarkable, and the structure was more relaxed and loose [1,25]. When the excitation wavelength was 295 nm (Fig. 3B), the maximum emission wavelength of casein did not present a red or blue shift. According to the literature, the major amino acids involved in the interaction of protein with hydrophobic compounds are Tyr, Phe, Trp, Leu, and Val. Moreover, reassembly enhanced the bond between α-TOC and hydrophobic protein groups. These structural and physicochemical properties of proteins facilitate their functionality as carriers if different bioactive compounds and micronutrients [3,43]. Esmaili et al. [23] encapsulated the hydrophobic curcumin with amphiphilic self-assembling protein, and as a result, the solubility, bioavailability, and antioxidant activity of curcumin increased. For this reason, the present study worked to improve the binding ability of this modified protein because hydrophobic interactions are major forces that occur during the interaction of α-TOC with protein.

3.5. FTIR characterization of casein after binding with α-TOC

The FTIR spectra of proteins exhibit a number of amide bands that represent different vibrations of peptide moieties, such as the bands corresponding to amide I (1,600–1,700 cm\(^{-1}\), mainly C = O stretch), amide II (1,600–1,500 cm\(^{-1}\), C–N stretch coupled with N–H bending mode), amide III (1,330–1,220 cm\(^{-1}\), C–N stretching vibration and N–H deformation of peptide group) [18,36,40].

The FTIR spectra of the α-TOC/CN nanoparticles is shown in Fig. 4. The peak positions of amide I bands are shifted in the infrared spectrum of casein after the interaction of casein with α-TOC. The changes to these peak positions and peak shapes demonstrated that the secondary structure of casein was altered, indicating the occurrence of an interaction between α-TOC and casein.

When both criteria I and II were fulfilled and the integral areas of the deconvoluted amide I bands to directly determine the relative amounts of different types of secondary structures. As shown in Fig. 5, Fourier deconvolution analysis and Gaussian curve fitting were performed to obtain detailed information about the protein structure.

Before estimation of the percentage content of each secondary structure, the component bands should be assigned. The band 1,650–1,670 cm\(^{-1}\) is typically assigned to the α-helix structure. In case of the β-sheet structure, the amide I band is generally in the range of 1,610–1,640 cm\(^{-1}\). The peaks of the random coil and β-turn structures can be found within the ranges of 1,640–1,650 cm\(^{-1}\) and 1,660–1,700 cm\(^{-1}\) [15,17]). A quantitative analysis of each secondary structure was performed considering the integrated areas of the component bands in amide I, as summarized in Table 3.

The ratio of α-helix to β-sheet structures in casein was 0.62; in case of the α-TOC/CN nanoparticles, the ratio decreased to 0.246–0.494. These results indicated that the flexibility of the internal structure of the protein increased.

3.6. Stability of α-TOC/CN nanoparticles

According to Table 4, the storage stabilities of the nanoparticles investigated under four conditions are significantly different. As the storage time increased from 1 to 6 h, the retention rate of the self-assembled nanoparticles decreased by 10.39% and 56.43%. Moreover, the retention rate of free α-TOC decreased by 1.21–1.26 times from 13.06% to 68.39% as the storage time in the refrigerator (4 °C) increased.

The retention rates of the self-assembled casein nanoparticles and the free α-TOC were 42.65% and 19.05% (6d) at room temperature, respectively. However, the storage stability exhibited the similar trends at room temperature and in a refrigerator (4 ± 2 °C), and the difference between the two stability values was not significant. However,
Fig. 5. The Fourier deconvolution analysis and Gaussian curve fitting.
compared to the first two treatments, temperature and oxygen has stronger effects on the thermal stability of the two samples (in an air dry oven at 50 °C), and the loss of retention rate (75.93%) was the most highest from 0 to 6 h.

When the samples were exposed to ultraviolet light, the retention rate exhibited a variation trend similar to those of the self-assembled nanoparticles and free α-TOC, and the retention rate decreased from 5.13% to 62.95% and from 7.85% to 61.37%, respectively. The retention rate of the self-assembled nanoparticles was significantly higher (p < 0.05) than that of the free α-TOC, which was ascribed to the fact that self-assembled nanoparticles can protect α-TOC from the degradation caused by ultraviolet light, oxygen, temperature. Lang et al. [45] observed similar results for casein, that is, the increasing stability of blueberry anthocyanins due to α-casein or β-casein was outstanding under thermal and photo conditions. α-Tocopherol decomposes easily through oxidation when exposed to mitigating conditions, such as high temperature, oxygen, and light [28]. Previous studies indicate that the stability of the α-tocopherol released from cold-set β-LG emulsion gels is considerably superior to that of free compounds [20].

3.7. Antioxidant activity testing

The effect of α-TOC/CN nanoparticles and free α-TOC on the formation of both LOOH and TBARS is shown in Fig. 6.

Both concentrations of α-TOC/CN nanoparticles were able to inhibit lipid oxidation in the oil-in-water emulsion, as determined by both LOOH and TBARS assays. With the passage of time, the concentrations of LOOH in the oil-in-water emulsion gradually increased to their maximum values with extension of the treatment time beyond 60 min. LOOH concentrations in the emulsion gradually increased to their maximum values with extension of the treatment time beyond 60 min.

Each value is expressed as mean ± standard deviation. The values not statistically different are accompanied by the same letter and the values statistically different with another letter as compared to control (Small letter represent intra-group, capital letter represent inter-group).

Fig. 6. Evolution of LOOH and TBARS in the four types of stabilized emulsions upon accelerated storage up to 180 min.
concentration of 100 mg/kg. Treatment with 200 mg/kg of nanoparticles led to smaller increases in the TBARS values of grape seed oil emulsion systems compared to those of the control samples. The reaction time could have promoted the decomposition of lipid hydroperoxides such that they did not accumulate but were instead converted to free radicals, leading to smaller increases in the TBARS values of grape seed oil.

From these results shown, we can conclude that during accelerated oxidation treatment, more rapid molecular degradation of the casein micelles occurred due to temperature and air, leading to the formation of oxidation radicals in oil. Lipid oxidation is one the major causes of food spoilage, and fats and oils in processed foods are typically used in emulsion form. Therefore, one strategy to inhibit lipid oxidation in oil-in-water emulsions is to use food additives that can bind and trap free radicals. Similar findings were reported for other oil emulsions, for example, at the oil-water interface, resveratrol can protect the oil by simply reacting with oxidizing agents. Esmaili et al. [25] observed similar results for curcumin, in that the antioxidative activity of curcumin encapsulated in Beta-CN was higher than those of the two free samples.

4. Conclusions

Changes in UV–Vis spectra were recorded with two maxima at wavelengths of 195.5–212 nm and 275.5–285.5 nm. The results of UV–Vis fluorescence spectrometry indicated that the secondary structure of casein changed in the presence of α-TOC. The results of proton spectra indicated that the nanoparticles exhibited the chemical shifts of conjugated double bonds. The fluorescence intensities of casein decreased gradually with increasing α-TOC concentrations, and the intrinsic fluorescence of casein was quenched by α-TOC in a static pattern. The size and PDI of the particles changed significantly with ultrasonic treatment (300 W, 5 min). Fourier deconvolution analysis and Gaussian curve fitting provided detailed information of the nanoparticles structures observed under different levels of treatment power (0, 100, 200, 300 W) and various treatment times (0, 5, 10, and 15 min). The ratio of α-helix to β-sheet secondary structures decreased from 0.62 to 0.246, which indicated that the structure of casein became more flexible. Under typical processing and storage conditions (thermal, photo, 20 ± 2 °C and 4 ± 2 °C), the stability of α-TOC increased due to its interaction with casein. The effects of casein on the antioxidant ability of α-TOC were investigated using LOOH and TBARS assays, and the results represent remarkable outcomes.
