ABSTRACT

Response of soybean crop toward N fertilizer in paddy fields is influenced by the cropping pattern. Present study was conducted for finding out the effect of two cropping pattern viz. rice-rice-soybean and rice-soybean-soybean and N fertilization on the production of soybean crops. Results of the study revealed that the cultivation of soybean after rice required higher amount of N fertilizer (30 kg N / ha of urea or 90 kg N / ha of ZA) to increase the grain yield from 0.5 t / ha (control) to 3.4 t / ha while in case of soybean after soybean cropping pattern soybean did not required any additional dose of N fertilizer for increasing the grain yield up to 3 t / ha.
1 Introduction

Soil nitrogen plays a crucial role in sustainable agricultural production but it can be disturbed by disturbing the supply of useable nitrogen (Santoso et al., 2001; Spiertz, 2010). It has been well reported that Indonesian paddy soil is generally deficient of N nutrient. According to Adisarwanto et al. (1998) paddy soil of East Java, Bali and NTB provinces have very low N content (0.07 to 0.25%). Similarly, in another survey Adisarwanto et al. (1999) reported that paddy soil of Ngawi and Banyuwangi have N status between 0.12 to 0.36%. Furthermore, paddy soil of Mojokerto, Banyuwangi and NTB have Entisol type of soil and showed NO3 concentration range between 5-70 mg/kg and N content between 0.08 to 0.19% (Adisarwanto & Subartina, 2000; Adisarwanto et al., 2001). Soil texture affects the rate of N2O losses, coarse-texture soil favor the loss of N2O while fine-texture soil has capacity to retain the N2O and decrease the loss of Nitrogen from the soil (Gentile et al., 2008). The decline in the intensity of tillage accompanied by an increase in crop diversification is very effective to increase the levels of total soil N (Al Kaisi et al., 2005). According to Dou et al. (2007) continuous cultivation soybean of had negative effect on the soil N level as compared to the sorghum–wheat–soybean and wheat–soybean cropping pattern.

Total N uptake by a plant also depends on the various environmental factor like types of soil, soil nature, total available nitrogen in soil and cropping pattern. Nature of soil and dose of fertilizers severely affect the fertilization process, according to Adisarwanto et al. (1998) urea is not a good nitrogen source for the Vertisol or Entisol paddy soil. It was reported that fertilization by urea @ 50 kg/ha did not increase soybean grain yield in Vertisol paddy field at Ngawi or Entisols at Jambegede and Banyuwangi (Adisarwanto et al. 1998). Even at the application of 100kg urea/ha on soybean followed by soybean (rice-soybean-soybean) and soybean followed by rice (rice-rice-soybean) also did not increase the grain yield (Suryantini & Kuntyastuti, 1998). However, the application of ZA at 50 kg/ha increased soybean grain yield by 0.26 t/ha (18%) in Entisol at Jambegede and by 0.36 t/ha (19%) in Vertisol at Ngawi (Riwanodja et al., 2001). Furthermore, the combination of 50 kg/ha urea and S-elementary 150 kg/ha also increased grain yield by 0.81 t/ha (86%) (Adisarwanto et al. 2001).

Similarly, Suryantini (2008) reported that the application of 50 kg/ha urea did not increase grain yield of soybean planted after rice. Conversely, in soybean planted after soybean (rice-soybean-soybean), the application of 50 kg urea/ha or Rhizobium inoculation at recommended rate increased the grain yield of soybean. Both nitrogen source (urea and Rhizobium) did not increase grain yield of soybean when there was manure residues, or given to soybean planted after rice (Suryantini & Rahmianna, 2001). Information regarding the effect of cropping pattern on nitrogen fertilization are in scarcity therefore present study have been conducted to find out the effect of two cropping pattern viz rice-rice-soybean and rice-soybean-soybean on the nitrogen fertilization.

2 Materials and Methods

The experiment was conducted in Entisol paddy fields at Jambegede Research Station Malang-Indonesia, during the dry seasons of 2010. Soybeans were planted after rice and after soybean crops in the cropping sequences of rice-rice-soybean and rice-soybean-soybean respectively. A randomized block design with three replications was used for present study. N fertilizer were applied at the rate of 0, 30, 60, 90, 120, 150, 180 and 210 kg N/ha from two sources, namely Urea and ZA (ammonium sulfate - (NH4)2SO4). Sulfur supplement (S) @ 210 kg N/ha was equated to all treatments using sulfur powder. This sulfur was also added in control namely without N and without N and S. The sulfur powder containing 85% S; while (NH4)2SO4 containing 21% N and 24% S and urea containing 46% N.

A composite soil samples was collect from each site before planting and analyzed for soil physical- chemical analysis (Table 1 and 2). Soil pH was measured in slurry (1:2.5 soil to water ratio) by glass electrode using an electronic pH, available P was measured by the method described by Bray 1. Total available N before planting was determined using the micro-Kjeldahl method while organic carbon was determined by the Walkley and Black wet oxidation method. Exchangeable bases were determined by ammonium acetate extraction, with Ca and Mg estimated by Atomic Absorption Spectrophotometer (AAS), and K by the flame photometer. Zn, Cu, Fe and Mn were measured by extraction using DTPA, with quantitative determination by AAS. Bulk density was determined by the cylinder method and total porosity was calculated from values of bulk and particle density. Clay size fraction was determined by the pipette method. The texture classes were defined according to the textural triangle by FAO.

Willis soybean varieties were planted in plots measuring 4 m x 5 m with a spacing of 40 cm x 10 cm, two plants/hill. Thinning was done at the age of 10 DAP (days after planting) and spared two plants/hill. Fertilizer N was applied twice (50% each) at planting and flowering in bands 10 cm from the plant rows. Weeding was done two times at 15 and 35 DAP, and watered every 20 days. Control of pests / diseases was done by monitoring the control threshold. Plants were harvested when 95% of pods had turned brown and fallen leaves. Data were collected at 60 DAP from samples of 5 plants per plot for shoot and root dry weight as well as number of branches per plant. Oven dried shoots were grinded homogenously and left at 400°C for 1 h for the development of ash, this ash samples were analyzed for estimating the total mineral including K, Ca, Mg, P, and S. Chemical analysis were done by energy-dispersive x-ray analysis (EDXA). While total N was determined by modified Kjeldahl digestion colorimetric method. At harvesting time 10 plants per plot were collected.
for measuring plant height, number of filled pods per plant and 100 seed weight, while the harvested plots of 3 m x 4 m was observed for number of harvested plants (plant population) and grain yield. Statistical analysis of data was carried out using standard analysis of variance (Gomez & Gomez, 1984). The significance of the treatment effect was determined using the F-test. To determine the significance of the difference between the means of treatments, Duncan Multiple Range Test (DMRT) was computed at the 5% probability level.

3 Results and Discussion

3.1 Rice-Soybean-Soybean Cropping Pattern

No significant difference was reported in Entisol paddy soil after rice and soybean cultivation. Soil after rice and soybean crops were poor in organic matter and macro nutrients likes N and S, but these soils were rich in P, K, Ca and Mg as well as for other micro nutrients (Table 1). The texture of the studied soil was clay loam and it has 17-19% water holding capacity and high cation exchange capacity (CEC). The saturated hydraulic conductivity (Ksat) for the studied soil was low (0.8 cm / hour) and the penetration of these soil was high (Table 2). Soybean after soybean grew well with a population nearly 460 thousand/ha approaching the optimum population. Optimal plant population is one of the requirements to achieve high yield (Table 4). Though conditions are favourable but fertilization by N did not have any significatory effect on shoot and root dry weight as well as number of branches. Dry weight of shoot and root reached 9.98 and 0.91 g/plant at the application of 180 Kg/ha and 150 Kg/ha respectively (totally equivalent to 4.53 t / ha stover). Increasing the dose of urea favor the plant growth characters. Application of urea and ZA @30 kg/ ha have positive effect on the plant growth characters and application at this level increased plant height from 40.3 cm (control) to 45.7 and 46.3 cm respectively and this treatments shows superiority over the other treatments of ZA. Further increases the levels of N and ZA have not showing any significant effect on the plant heights and number of branches/plant (Table 3).

Table 1 Chemical properties of Entisol paddy soil in rice-rice-soybean and rice-soybean-soybean cropping system (0-20 cm depth).

| Chemical properties | Rice-Rice-Sooybean | Rice-Sooybean-Sooybean |

Data are mean of five plants; ± Standard Error of mean; Values without common letters differ significantly at LSD P<0.05; Non Significant (NS) value on Duncan Multiple Range Test (DMRT) was computed at the 5% probability level
Application of N fertilizers caused increases in the soybean grain yield and weight of 100 seeds and it is significantly differ than the control. Soybean grain yield and weight of 100 seed were higher and reached an average of 2.99 t/ha and 10.54 g respectively (Table 4). Similarly number of pod was also reported at par or higher than the control and it reach up to 50.8 pod/plant on the application of urea at 180 Kg N/ha. Result of the study revealed that Application of urea shows superiority over the application of ZA (Table 4). While the other doses of N fertilizers did not show significant increases the number of pod as compared to the dose of 180 kg/ha. Lack of crop response to fertilizer N presumably related with N fixation of indigenous *Rhizobium*. Generally the soil frequently used for soybeans plantation contain enough *Rhizobium* population. According to Salvagioti et al. (2008) a negative exponential relationship was observed between N fertilizer rate and N2 fixation when N was applied in the top 0–20 cm of soil or on the soil surface. They reported highest N fixation (337 kg/ha) in the treatment without chemical N fertilization or on the soil surface. They reported highest N fixation (337 kg/ha) in the treatment without chemical N fertilization and N2 fixation when N was applied in the top 0–20 cm of soil or on the soil surface. They reported highest N fixation (337 kg/ha) in the treatment without chemical N fertilization and N2 fixation when N was applied in the top 0–20 cm of soil or on the soil surface.
3.2 Rice-Rice-Soybean Cropping System

Result of the study clearly suggested that cropping pattern having soybean after rice shows better soybean growth than the soybean after soybean. The average plant height reached 67.1 cm, while the average shoot weight was reported 9.04 g/plant and it was higher than the control (Table 5). However shoot dry weight, plant height and number of branches was not affected by N fertilizer. Among the two nitrogen sources ZA shows superiority over the urea but it is not significantly differ. With respect to the response of N fertilizer, addition of sulfur powder @ 282 kg / ha (to equalize the content of S in the treatment of 210 kg N / ha of ZA) in the treatment without N increased the weight of 100-seeds from 10.16 to 10.40 g. Combination of N and S fertilizers did not have any significant effect on the weight of 100 seeds. Similarly, N fertilizer did not increase number of pods and weight of seeds per plant (Table 6). The positive influence of sulfur on the weight of 100 seeds might be related to its role in seed production and quality especially in the formation of seed proteins (Jamal et al., 2010; Devi et al., 2012; Choudhary et al., 2014).

Nitrogen fertilization had no effect on grain yield in case of grown soybean after soybean while a positive effect on grain yield was obtained in the condition of grown soybean after rice. Grain yield of soybean grown after rice without N fertilizer was 2.84 t / ha. The application of urea at 30 kg / ha increased grain yield by 0.58 t/ha (20%) to 3.42 t / ha, and it was the highest grain yield level while the using of ZA @ 90 kg / ha increased the grain yield by 0.54 t / ha (19%) to 3.38 t / ha (Table 6). These findings were different than the findings of Kuntyastuti et al. (2007) those have reported that N fertilization @ 30-210 kg / ha in clayey loam textured soils poor of N did not increase grain yield of soybean grown after rice (rice-rice-soybean) as well as after soybean (rice-soybean-soybean).

The results of this study add to the fact that response of soybean to fertilizer N has been inconsistent (Gan et al., 2003; Barker & Sawyer, 2005) which is related to large variation in indigenous soil N supply such as net soil N mineralization, irrigation, atmospheric deposition, or other factors affecting yield responses to N (Salvagiotti et al., 2008). Although growth and grain yield of soybean grown after rice was better than soybean grown after soybean but the N uptake in both fields were relatively similar, as well as other nutrients (Table 7 and 8). This indicates that cropping pattern had no effect on nutrient uptake by soybean plants (Table 1).

Conclusion

Soybean planted after rice in rice-rice-soybean cropping pattern required 30 kg N / ha of urea or 90 kg N / ha of ZA to increase grain yield by 0.5 t / ha while soybean planted after soybean in rice-soybean-soybean cropping pattern did not require N fertilizer.

Acknowledgment

The authors thank Prof. Sudaryono in the Indonesian Legume and Tuber Crops Institute (ILETRI), for his valuable comments on the manuscript
