Abstract

Background: To identify the medial open-wedge high tibial osteotomy (MOWHTO) prognostic factors with wedge-shaped spacer implantation (spacer-type MOWHTO) for varus medial compartment knee osteoarthritis.

Methods: Patients who underwent spacer-type MOWHTO between August 2018 and September 2019 were prospectively enrolled in this study. Patients were divided into two groups based on Western Ontario and McMasters University Osteoarthritis Index (WOMAC) scores of 40 points at 1 year postoperatively: the effective group (n=88, 84.6%), with post-WOMAC scores 40 or less, and the invalid group (n=16, 15.4%), with post-WOMAC scores more than 40. The variables assessed at baseline and 1 year postoperatively including age, sex, body mass index (BMI), Kellgren-Lawrence (K-L) grade, hip-knee-ankle angle (HKAA), medial proximal tibial angle (MPTA), posterior tibial slope angle (PTSA), Blackburn-Peel index (BPI), duration of symptoms and WOMAC score, were compared. Prognostic factors were analyzed using logistic regression, and the corresponding odds ratios were also calculated.

Results: A total of 104 patients were enrolled in the study protocol at 1 year postoperatively. The WOMAC score decreased from 72.39±12.95 at baseline to 20.06±12.96 at 1 year postoperatively. The preoperative varus was corrected to a neutral position or to mild valgus. In addition, the PTSA was decreased. At the same time, the patellar height was not significantly changed postoperatively. Univariate analysis revealed that the significant predictors of the WOMAC score were age >70 years, BMI >30 kg/m², K-L grade IV, and pre-HKAA >10° (P<0.1 for all). Multivariable logistic regression analysis revealed that age>70 (OR=4.861) and K-L grade IV (OR=6.590) were significantly associated with the WOMAC score at 1 year postoperatively.

Conclusion: Spacer-type MOWHTO is an effective treatment for osteoarthritis with varus deformity. The prognostic factors for spacer-type MOWHTO were age and K-L grade.

Level of evidence: III

Background

Osteoarthritis (OA) is one of the major causes of mobility disorders and disability and affects over 10% of men and 13% of women older than 60 years[1, 2]. OA is approximately 10 times more frequent in the medial knee compartment than in the lateral compartment, and varus (but not valgus) alignment increases the progression of knee OA and eventually leads to the need for total knee arthroplasty (TKA) [3–9]. Medial open-wedge high tibial osteotomy (MOWHTO) is a highly effective surgical procedure in patients younger than 55 years with OA[5, 10–12]. It works by relocating the weight-bearing axis from the medial pathological compartment to the lateral healthy joint space. The main advantages of MOWHTO are joint preservation and minimal trauma. Moreover, MOWHTO achieves pain relief and improvement of knee function, which can postpone the need for TKA by 7 to 20 years[13–15].
MOWHTO is generally performed through an oblique incision on the medial side of the tibia while preserving the lateral tibial cortex[16, 17]. Zhang et al. recently reported a more minimally invasive and simple osteotomy in MOWHTO. This new type of MOWHTO used a novel absorbable wedge-shaped spacer composed of 30% β-tricalcium phosphate and 70% poly (lactic-co-glycolic acid) instead of a locking compression plate system[18]. Compared with conventional MOWHTO, this novel method has a lower cost, avoids the need for secondary surgery for fixation removal, and improves in radiographic appearance and knee function during follow-up[18, 19]. Essentially, this type of absorbable spacer is a bone graft substitute that provides support in the open wedge without rigid internal fixation; however, the longitudinal stability of the cut tibia cannot be guaranteed. Zhang et al. also performed simultaneous proximal fibular osteotomy, which provides a better valgus orthopedic effect but may cause more complications or defects[18, 19].

Considering the advantages of this novel osteotomy method, we hypothesized that the prognostic factors for MOWHTO with spacer implantation (spacer-type MOWHTO) would differ from those for conventional MOWHTO with internal fixation. Thus, spacer-type MOWHTO may have more limited and strict indications than conventional MOWHTO. Additionally, it is unclear whether the results of spacer-type MOWHTO are significantly influenced by the pre- and postoperative radiographic axes. Therefore, it is necessary to define clear prognostic factors for evaluation prior to spacer-type MOWHTO. The objective of this prospective study was to identify the prognostic factors for successful spacer-type MOWHTO.

Materials And Methods

Study population

Study approval was obtained from the research ethics committee (QYFYWZLL26146). From August 2018 to September 2019, a total of 111 spacer-type MOWHTO surgeries were performed by a single surgeon. Patient characteristics and surgical data were collected. All patients were asked for their consent to participate in the study before surgery. The inclusion criteria were as follows: (1) spacer-type MOWHTO performed during the aforementioned study period, (2) no history of knee surgery or trauma, (3) unilateral medial compartment knee OA with < 15° varus malalignment on weight-bearing full-leg anteroposterior radiographs, (4) K-L grade II–IV, (5) knee range of motion of more than 20° in extension and 100° in flexion, and (6) minimum follow-up of 1 year with clinical outcome evaluation. We excluded 7 patients. Two patients required a plate to stabilize the tibia during the surgical procedures because an unstable hinge fracture. Two patients reoperation needed because of tibial fractures due to a fall during the rehabilitation process. In addition, 3 patients were excluded due to being considered lost to follow-up.

Surgical procedures

The same doctor performed the operation under general anesthesia. The whole surgical procedure was composed of two main steps, including proximal fibular osteotomy and high tibial osteotomy. Proximal fibular osteotomy: A 3 cm longitudinal incision was made approximately four fingerbreadths below the head of the fibula to avoid iatrogenic injury of the peroneal nerve. The proximal fibular shaft was exposed
by splitting the septum between the soleus and peroneus. Then, the fibula with a length of approximately 2 cm was cut by using a saw blade, and the peroneal nerve was protected from damage by using a retractor (Fig. 1(a) and (b)). Finally, the incisions were irrigated with saline.

High tibial osteotomy: A 4 cm longitudinal incision was made 2 cm inferior to the knee which extended along the posterior one-third of the tibia. The skin, subcutaneous tissue and deep fascia were cut to expose the pes anserinus. The periosteum was cut between the patellar tendon and pes anserinus to expose the proximal tibia. A 3.5 mm guidewire was inserted 3 cm below the knee joint towards the head of the fibula to determine the osteotomy plane (Fig. 1(c)). Then, the proximal tibia was drilled on the osteotomy plane with a multi-hole parallel guiding apparatus and Kirschner wires (Fig. 1(d) and (e)). After that, the holes in the tibia were connected using a chisel. Test models of different thicknesses were successively hammered into the osteotomy plane (Fig. 1(f)). The mechanical axis of the lower extremity was assessed under fluoroscopic guidance to guarantee the preoperative varus deformity was corrected to a slight valgus or to neutral position. Then an absorbable spacer implantation with suitable size was implanted. There were numerous holes and screws on the absorbable spacer that could accelerate bone union and enhance the stability of the osteotomy plane. If no unstable hinge fracture was found under fluoroscopy, the incisions were sutured after irrigation with normal saline. A buttress plate was needed to stabilize the tibia during the surgical procedures, if an unstable hinge fracture was found (Fig. 2).

Preoperative preparation and postoperative rehabilitation

Preoperative physical preparation: All patients completed a 3-week preoperative high-intensity isokinetic resistance training program focusing on quadriceps and hamstring strength. Postoperative rehabilitation: Antibiotics were administered within 24 hours after surgery. Patients were encouraged to exercise joint function on the bed to avoid joint stiffness and deep vein thrombosis. The isokinetic resistance training program focusing on quadriceps and hamstring strength was performed on the duration before full weight-bearing was allowed. Partial weight-bearing with crutches was initiated at 6 weeks postoperatively. Full weight-bearing was allowed when there was evidence of bone union at the osteotomy site (almost 3 months postoperatively) (Fig. 3). For patients with a BMI > 30 or severe osteoporosis, the time to full weight-bearing was delayed.

Radiological measurements

A radiological evaluation was performed preoperatively and at the last follow-up after surgery (Fig. 4). All radiological data were recorded by a dedicated radiology technician under the supervision of two orthopedic surgeons who did not participate in the surgery. The radiographic evaluations entailed the assessment of full-length standing hip-to-ankle radiographs and anteroposterior and lateral knee radiographs. The medial proximal tibial angle (MPTA), hip-knee-ankle angle (HKAA), posterior tibial slope angle (PTSA), and Blackburn-Peel index (BPI) were measured on the radiographs. The HKAA was defined as the angle between mechanical axis of the femur and the tibia. The MPTA was defined as the medial angle between the tibial mechanical axis and a line connecting the tibial plateaus. The PTSA was defined as the angle between a line connecting the apex points at the anterior and posterior borders of the lateral tibial plateau and a line perpendicular to the posterior tibial cortex. The BPI was defined as the
perpendicular distance from the lower margin of the patellar articular surface to the tibial plateau line divided by the length of the patellar articular surface on lateral radiographs.

**Statistical analysis**

Normally distributed variables are expressed as means and standard deviations, and categorical variables are presented as frequencies. The Kolmogorov-Smirnov normality test was used before statistical analysis to determine whether to use parametric tests. The radiologic measurements between the two groups were compared with independent t-tests. Analysis of categorical or dichotomized data employed the chi-squared test. Multiple logistic regression analysis was performed for the variables with a $P<0.1$ in the univariate analyses. Odds ratios (ORs) and 95% confidence intervals (CIs) were calculated. Intraclass correlation coefficients (ICCs) with 95% CIs were used to evaluate the reproducibility or radiographic measurements, and ICCs >0.75 were considered to represent excellent agreement. All computations were performed using standard software (SPSS 23.0; SPSS Inc, Chicago, IL); $P<0.05$ was considered statistically significant.

**Results**

**Demographics of patients**

A total of 104 patients (36 males and 68 females) with a mean age of $61.67\pm7.71$ years (range, 46-78 years) were eligible for our study protocol. Further details of the characteristics of the study cohort and the study protocol are shown in Table 1.

**Table 1. Patients Demographic Date**

| Characteristic                        | Value          |
|--------------------------------------|----------------|
| No. Of patients                      | 104            |
| Age (y)                              | $61.67\pm7.71$ |
| male: female                         | 36:68          |
| Body mass index (kg/m²)              | $28.08\pm3.35$ |
| K-L grade II/III/IV                  | 58/30/16       |
| Duration of symptoms (y)             | $6.85\pm5.51$  |

BMI, body mass index; K-L grade, Kellgren - Lawrence;

Values are shown as mean ±standard deviation.

**Clinical and radiographic outcomes**
The WOMAC scores were significantly decreased at 1 year after surgery compared with the preoperative baseline values ($P<0.001$). The postoperative HKAA and MPTA were significantly corrected compared with preoperative indicators. All preoperative varus deformity was corrected to a slight valgus or to neutral position, causing a significant decrease in the varus angle (Fig. 5). Moreover, the PTSA was decreased, and the patellar height was not significantly changed postoperatively (Table 2). For all preoperative and postoperative radiologic measurement data, the reproducibility among radiological values was excellent (ICCs=0.845-0.922), and the interobserver agreement for K-L grades of OA was strong ($\kappa=0.822$).

**Table 2. Comparison of pre-operative and post-operative of clinical results and radiologic parameters**

|                | Preoperative | Postoperative | $P$-Value |
|----------------|--------------|---------------|-----------|
| HKAA (°)       | 7.58±3.28    | -2.05±1.58    | <0.001    |
| MPTA (°)       | 85.95±2.35   | 92.31±2.46    | <0.001    |
| PTSA (°)       | 9.27±3.54    | 7.33±3.34     | <0.001    |
| BPI            | 0.75±0.11    | 0.73±0.13     | 0.084     |
| WOMAC score    | 72.39±12.95  | 20.06±12.96   | <0.001    |

WOMAC, Western Ontario McMaster University Osteoarthritis Index Scales; HKAA, hip-knee-ankle angle; PTSA, The posterior tibial slope angle; MPTA, Medial proximal tibial angle; BPI, the Blackburn-Peel index; Values are shown as mean ±standard deviation.

**Risk factor analyses of postoperative results at 1 year**

Among the 104 knees, 16 (15.4%) knees had a total WOMAC score > 40 points, and 88 (84.6%) knees had a total WOMAC score $\leq$ 40 points at 1 year after surgery. According to the total WOMAC scores, patients were divided into 2 groups: WOMAC scores $\leq$ 40 points were classified into the effective group and patients who had WOMAC scores >40 points were classified into the invalid group. By comparing the variables between the two groups, the mean values of age, BMI, pre-HKAA and percentage of K-L grade IV were significantly higher in the invalid group (Table 3). Univariate analysis revealed that preoperative age $>$70, BMI $>$30, pre-HKAA $>$10° and K-L grade IV were significant predictors for multiple logistic regression analysis ($P<0.1$ for all) (Table 4). Multivariable logistic regression analysis showed that age $>$70 (OR=4.861) and K-L grade IV (OR=6.590) were significantly associated with the total WOMAC score at 1 year after surgery (Table 5).

Discussion

MOWHTO reportedly achieves significant improvements in pain and function, slows down the progression of OA, and postpones the need for TKA[5, 8, 10, 14–18]. However, this surgical treatment also causes numerous problems during follow-up. First, the treatment effect seems to deteriorate over time, with reported survival rates of 51–97.6% at 10 years postoperatively[5, 10, 20–26]. Second, complications occur after MOWHTO in 10–50% of patients[5, 27]. Although there are few serious adverse events, the incidence of complications is higher after MOWHTO (28%) than that after TKA (7%)[28, 29]. Third, MOWHTO is not the ultimate treatment for OA of the medial knee compartment, and the outcome of TKA performed after MOWHTO may be influenced by factors such as the patellar height, condylar offset, and/or tibial inclination angle[19]. Therefore, clinical treatment must be guided by strict indications and predictors, especially for the novel spacer-type MOWHTO.

Because of the differences between surgical procedures, the prognostic factors of spacer-type MOWHTO may differ from those of conventional MOWHTO with internal fixation[18]. In our study, spacer-type MOWHTO obtained better results in patients with a younger age and lower K-L grade, while age > 70 years and K-L grade IV were identified as risk factors for dissatisfaction following spacer-type MOWHTO. Previous studies have shown a correlation between tibial radiological values and clinical signs, but no study has evaluated the effect of these indexes on the outcome of spacer-type MOWHTO. The HKAA, MPTA, and PTSA are corrected to a specific high tibial osteotomy standard position to ensure the attainment of anatomic postoperative lower limb alignment and tibial plateau retroversion. Some studies have reported that a small HKAA (< 15°) is more suitable for spacer-type MOWHTO[18, 19]. Therefore, we excluded patients with radiographic measurements that were outside the ranges suggested in the literature. This means that more stringent preoperative planning is needed for spacer-type MOWHTO than for conventional MOWHTO to ensure efficacy and minimize complications.

Although the incidence of knee OA was significantly higher in women than in men, our study found that gender was not a significant prognostic factor for spacer-type MOWHTO[5, 10]. Furthermore, the long-term history did not affect the frequency of poor results.

Age was a significant predictive factor of a poor outcome after spacer-type MOWHTO. For patients older than 70 years, it is difficult to achieve ideal knee functional recovery after surgery. Long-term incomplete weight-bearing (approximately 3 months) and osteoporosis may be the main causes of muscular atrophy and decreased physical activity[5, 30, 31]. After surgery and muscle strength recovery were still a challenge for elderly patients, even though muscle training was used in patients. Older patients often have more severe osteoporosis, which increases the risk of intraoperative hinge fractures. Advanced age and osteoporosis were also risk factors that affect the healing of the osteotomy plane, which can delay
the complete weight-bearing time. Furthermore, the increased recovery time resulting in activity reduction increases the risk of lower extremity thrombosis and decreases lung function.

In our study, the outcome of spacer-type MOWHTO was much worse for patients with severe knee OA with a K-L grade of IV than for patients with a K-L grade of II-III. This suggests that the outcome of spacer-type MOWHTO was affected by degeneration of knee joint. Severe knee lesions such as patellofemoral arthrosis[32], synovitis, cartilage defects or ligamentous knee instability[32] may affected the surgery outcome even though lower limb alignment was completely corrected. Similarly, previous studies have reported that patients with K-L grade IV OA achieve unsatisfactory results after conventional HTO. Studies have shown that inflammatory factors in the joints play a more important role than dynamics in the late clinical manifestations of knee OA[33–35].

Although BMI was not considered to be an independent risk factor for spacer-type MOWHTO, we thought that patients with a high BMI had a higher risk of surgical complications. The incidence of complications such as loss of valgus correction angle due to loosening and prolapse of the implantation, hinge fracture, persistent postoperative pain and numbness, and reoperation was higher in patients with a high BMI. However, for conventional MOWHTO, the locking compression plate provides reliable stability that enables the cut tibia to bear body weight[17]. Due to the instability of the medial tibia after spacer-type MOWHTO, the placement of too much weight on the wedge cross end can cause implantation prolapse or hinge fracture.

Compared with traditional MOWHTO, this novel method has many advantages, such as a lower cost, avoiding the need for secondary surgery for fixation removal, maintaining the patellar height to avoid degeneration of the patellofemoral joint[10, 29, 36–38] and decreasing the posterior tibial slope. However, the longitudinal stability of the cut tibia cannot be guaranteed. Patients needed to experience long-term incomplete weight-bearing (approximately 3 months) to guarantee a great bone union and stability of the osteotomy plane. This was a shortcoming of this novel method, which may have affected the postoperative results of some patients and caused other complications[39]. It might be expected that long-term incomplete weight-bearing would produce muscular atrophy, loss of proprioception, and decreased physical activity[40]. Therefore, strict surgical indications and appropriate pre- and postoperative rehabilitation plans are essential.

Our study had several limitations that may have influenced the results. First, the follow-up duration was relatively short, with a maximum of 1 year. Thus, the follow-up duration was too short to enable the accurate evaluation of the outcome of the spacer-type MOWHTO but can be used to evaluate the short- or medium-term curative effect. Long-term follow-up studies are needed to confirm the predictive factors affecting the clinical outcomes of spacer-type MOWHTO. Second, fibular osteotomy was performed during spacer-type MOWHTO which may have impacted the clinical outcomes. However, recent studies have reported good outcomes after fibular osteotomy.

Conclusion

The results of our study showed that age, K-L grade and BMI are the main prognostic factors associated with satisfaction following spacer-type MOWHTO, which supports our hypothesis. Spacer-type MOWHTO seems most suitable for younger, thinner patients with less severe OA of the medial compartment. Therefore, to ensure appropriate patient expectations regarding surgical outcomes, these factors should be considered when choosing between spacer-type MOWHTO or conventional MOWHTO. The patients should be fully informed about the advantages and disadvantages of the two surgical procedures.

Declarations

Ethics approval and Consent to participate: All procedures performed in the study involving human participants were in accordance with the declaration of Helsinki. Statement on ethics approval and all experimental protocols were approved by the Human Ethics Committee of Affiliated Hospital of QingDao University. The ethics approval number was QYFYWZLL26146. Written informed consent was obtained from all patients included in the study.

Consent for publication: Not applicable.

Availability of data and material: All data generated or analysed during this study are included in this article.

Competing interests: The authors declare that they have no competing interests

Funding: This study was supported by National Natural Science Foundation of China (NO.31802022).

Author's contributions: All authors contributed to the study conception and design. WC contributed to the data collection. WM did the statistical analysis and prepared the Tables. Material preparation were performed by JC and YZ. The operation was performed by YZ. The first draft of the manuscript was
written by FW, and all authors commented on previous versions of the manuscript. TY provided critical
review and substantially revised the manuscript. All authors read and approved the final manuscript.

Figures

![Figure 1](image_url)

**Figure 1**

Surgical procedures of spacer-type MOWHTO are presented. The proximal fibular shaft is exposed by splitting the septum between the soleus and peroneus (a). The resected proximal fibula (b). A 3.5 mm guidewire was inserted 3 cm below the knee joint towards the head of fibula to determine the osteotomy
plane (c). The proximal tibia was drilled on the osteotomy plane with a multihole parallel guiding apparatus and Kirschner wires [(d) and (e)]. Test models of different thicknesses are hammered into the osteotomy plane (f).

Figure 2

A buttress plate is used for patients with unstable hinge fracture during the surgical procedures.
Figure 3

Bone union at the osteotomy site is shown on supine anteroposterior radiographs 3 days after surgery (a) and 4 months after surgery (b).
Figure 4

Definition and measurement of HKAA, MPTA, PTSA and BPI. Angle $\alpha$ expresses the HKAA, angle $\beta$ expresses the MPTA (a), and angle $\gamma$ expresses the PTSA (b). The Blackburn-Peel index (BPI) is equal to $b/a$ (c).
Figure 5

Images a, b, and c show changes in lower limb alignment preoperatively and 6 months and 12 months after surgery, respectively.
