Abstract

Purpose

Outcomes for different subtypes of aortic stenosis (AS) after transcatheter aortic valve implantation (TAVI) are still subjects of debate. The aim of the study was to evaluate the prognostic impact of baseline flow rate (F) and mean gradient (G) on survival after TAVI.

Methods

From 2008 to 06.2017, TAVI was performed in 300 cases (127 men, 173 women, age 80.0±5.8 years) with severe AS. Follow-up was at least 3 years. Mortality tracking was 100%. Patients were divided into high gradient (HG: 237), low-flow low-gradient (LF-LG: 41), paradoxically low flow-low gradient (PLF-LG: 9) and normal flow-low gradient (NF-LG: 13) groups. Primary endpoint was 30-day, 1-year and 3-year all-cause mortality (M).

Results

NF-LG had better prognosis (M: 30d 0, 1-year: 7,7%, 3-year: 46,2%). In HG patients mortality was low in the 1st year (30-day: 3,8%, 1-y: 14,3%), but higher (62,8%) after 3 year. PLF-LG had intermediate outcomes (30-day 0, 1-year 22,2%, 3-year 55,6%). LF-LG had the highest mortality (30-day 12,2%, p=0,03, 1-year 34,2% p=0,005, 3-year 75,6% p=0,009 vs.HG) and relative risk (2,44 [1,34-4,42] p=0,003 vs.HG). Independent predictors of 1-year mortality were only Grade 2+ paravalvular regurgitation (p=0,04) and severe renal dysfunction (p=0,04).

Conclusions

TAVI survival is determined by the guideline-defined subtype of AS. Low flow – low gradient AS is associated with worse prognosis, therefore these patients need careful management after TAVI.

Introduction:

Severe aortic stenosis (AS) is the most common valvular disease with considerable impact on morbidity and mortality, and with increasing prevalence. According to the current guidelines, severe AS is defined with aortic valve area (AVA) 1.0 cm², aortic mean gradient 40 mmHg, and peak aortic velocity 4.0 m/s [1.].

In case of low output lower mean gradient may occur. Hence, beyond the classical definition, different clinical entities of AS were later described [2.-4.]. Each type of AS is characterized by different clinical presentation and prognosis [4.-6.]. Stages of AS and current recommendations for intervention are based primarily on AVA, mean Gr and peak CW jet velocity, and secondarily on stroke volume index (SVI) and LVEF [7.,8.]. In the last decade there was a growing evidence, that transvalvular flow can be more important than EF, therefore a new classification of AS became reasonable [9.]. This idea is now widely accepted and incorporated in the current guidelines [7.,8.]. Nevertheless, all patients with severe symptomatic AS have poor prognosis without valve replacement [10.]. For patients with prohibitive, high
or intermediate operative risk, transcatheter aortic valve replacement (TAVI) can be an alternative solution [11.].

Despite the favorable outcome and hemodynamic results after TAVI, a considerable proportion of patients die within the first 2 years [11.]. Therefore, it is of particular importance to identify patients who may benefit from this treatment indeed. Surgical scores have not been validated to predict mortality after TAVI [12.]. Further risk scores have been developed, specifically for TAVI patients [13.-14.], however, these systems are not widely accepted and used. Several studies revealed that reduced SVI may be an independent predictor of mortality after TAVI [15.,16.]. In addition, there have been similar conclusions regarding the impact of low ejection fraction (EF) and low gradient (LG) on outcomes after TAVI [17–19.]. Further extension of indication for TAVI can be expected in the near future in a significant part of low-risk AS patients, considering the positive results of the latest large low-risk TAVI trials [20.21.]. In this group long-term success is determined mostly by initial hemodynamic (i.e. echocardiographic) parameters and periprocedural complications rather than severe comorbidities.

The objectives of this study were to evaluate the prognostic impact of different SVI – gradient patterns on outcomes of TAVI, as well as the changes in left ventricular function.

Methods:

Patients and Procedures

The present study included all (n 300) patients between 2008 and June 2017, with symptomatic (NYHA class II.-IV.) severe AS (mean Gr ≥ 40 mm Hg, or an aortic valve area of < 1.0cm, or < 0.6 cm²/m²) undergoing TAVI in our Institute. All patients were evaluated for TAVI by the ‘Heart Team’. In all patients, clinical assessment, transthoracic echocardiography, coronary angiography and multislice computed tomography were performed before the procedure.

The present study was accepted by the local ethics committee and all patients provided written informed consent.

Clinical and echocardiographic examinations of patients were performed within 7 days before TAVI and 12 months after implantation. All patients were followed for at least 3 years. Mortality tracking was achieved in 100% of patients. Mortality data were obtained in all cases from the Registry of the National Health Care System.

The primary endpoints were 30-day, 1-year and 3-year all-cause mortality after TAVI. In addition, secondary endpoint was the change of LVEF in the survivors.

Patients were subdivided into groups depending on their SVI – Gr pattern. High gradient was considered if the mean Gr was >/= 40 mmHg, and low Gr if it was < 40 mmHg. Low flow was defined with SVI </= 35 ml/m², and normal flow with SVI >35ml/m². Patients were divided into four groups:
HG: high gradient; regardless of EF or SVI

LF-LG: low flow - low gradient; and LVEF < 50%

PLF-LG: low flow - low gradient and LVEF >/= 50%

NF-LG: normal flow-low gradient.

Transcatheter aortic valve implantation

TAVI was performed in 300 patients (native AS, n 294; degenerated bioprosthesis, n 6). Medtronic CoreValve prosthesis was inserted in 285 cases, Edwards-Sapient valve in 2 cases, Medtronic Engager in 8 cases and Lotus prosthesis in 7 cases. Access site for TAVI was transfemoral in 287 cases, transapical in 8 cases and direct transaortic in 5 cases.

Echocardiography

Comprehensive 2-dimensional and Doppler echocardiographic studies were performed on ultrasound equipment IE33, Phillips Healthcare, Andover, MA in accordance with the European Association of Echocardiography guidelines [1., 22.].

For each study, multiple transducer positions were used routinely for measurement of aortic gradient. Heart valve insufficiencies were evaluated according to the recommendations of the European Association of Echocardiography. Left ventricular ejection fraction was measured by biplane Simpson method from four- and two-chamber views.

All TAVI implantations were monitored with transesophageal echocardiography. Besides valve positioning, hemodynamics and possible complications, we carefully evaluated the cause and the degree of paravalvular aortic regurgitation (AR) according to the WARC-2 criteria [23.]. Measuring the circumferential extent of paravalvular jet(s) mild AR was defined < 10%, moderate AR 10–29% and severe AR >/= 30%. Different grades of paravalvular AR are illustrated on Fig. 1..

Statistical analysis

Numerical values are expressed as mean + standard deviation (SD) or median. Continuous variables were compared between groups using an unpaired t-test (for normally distributed variables). Continuous variables were compared using the paired Student’s t-test before and after TAVI. Time-to-event data analysis was done using the Cox proportional hazards model. Survival curves were constructed for time-to-event variables using Kaplan-Meier estimates and compared by the log-rank test. The association between mortality and baseline clinical, echocardiographic and periprocedural variables was assessed with the use of Cox proportional hazard analysis. Variables with a p value < 0.10 in univariable analysis were entered into the multivariable model. All reported probability values are two tailed, and P < 0.05 was
considered statistically significant. Analyses were performed with the SPSS statistical software package (version 24.0).

**Results:**

Patient characteristics:

The mean age of patients (173 women, 127 men) was 80,0+/-5,8 years. Because of porcelain aorta 16 patients had contraindication for open-heart surgery. In the 284 high-risk cases the logistic EuroSCORE was 19,7+/-12,6. The AVA was 0,54+/-0,16 cm$^2$, the mean Gr 50,9+/-17,6 mmHg and the mean EF was 54,3+/-14,0%.

Time to follow-up was median 34 months (0-115 months)

The HG AS subgroup included 237 cases (79%), the LF-LG AS 41 cases (13,67%), while only 9 patients (3%) fulfilled PLF-LG and 13 (4,33%) NF-LG criteria. Subgroups are illustrated in Table 1.

| HG          | NF-LG                          |
|-------------|--------------------------------|
| Mean gradient $\geq 40$ mmHg | SVI $> 35$ ml/m$^2$             |
| N: 237 (79%) | Mean gradient $< 40$ mmHg       |
|             | N: 13 (4,33%)                  |
| PLF-LG      | LF-LG                          |
| LVEF $\geq 50\%$, SVI$\leq 35$ ml/m$^2$ | SVI $\leq 35$ ml/m$^2$ |
| Mean gradient $< 40$ mmHg | Mean gradient $< 40$ mmHg       |
| N: 9 (3,0%)  | N 41 (13,67%)                  |

HG AS patients were significantly older, had smaller AVA,. From the 237 HG cases 127 (53,6%) had low SVI. In the LF-LG group the prevalence of NYHA class IV., myocardial infarction, peripheral artery disease was higher, and these patients had larger end-diastolic and end-systolic volumes and lower EF compared to HG-AS group. In the PLF-LG group the ESV was smaller and the EF was higher than in the HG patients. In the NF-LG group the EDV and ESV was significantly higher than in the HG group. Baseline clinical and hemodynamic characteristics of patients and the differences between groups are shown on Table 2.

Mortality after TAVI:

Periprocedural death occurred in 1 case in the HG group (0,33%), 30-day all-cause mortality was 4,33 % (n = 13), 1-year mortality was 17,0% (n = 51), and primary endpoint was reached at 3-year in 62,0% (n = 186). HG AS had better 30-day, 1-year and 3-year mortality compared to LF-LG (30d: 3,8% vs 12,2% p = 0,03, 1-year 14,3% vs 34,2% p = 0,005 3-year 62,2% vs. 75,6% p = 0,009). PLF-LG patients had intermediate outcomes (1-y 22,2%, 3-y 55,6%). The NF-LG group had the best outcomes, but because of the small number of endpoints the difference was not significant. The differences in mortality rates between subgroups are demonstrated on Table 3.

### Table 3
**Mortality of the subgroups**

|              | Periprocedural | 30. day | 1 year     | 3 year     |
|--------------|----------------|---------|------------|------------|
| HG 237       | 1 (0,33%)      | 9 (3,8%)| 34 (14,3%) | 149 (62,2%)|

p: vs. HG

Kaplan Meier survival curve of the whole patient group is demonstrated on Fig. 2. Survival curves of different subgroups of AS are shown on Fig. 3. Differences in survival between HG and LF-LG groups is demonstrated on Fig. 4.

Predictors of mortality:

Because of the course of mortality rates, we considered of importance the assessment of 1-year hazard ratios of different subgroups, as well as several degrees of EF, flow, Gr, AVA and comorbidities. Different degrees of left ventricular dysfunction and low gradient had significantly higher risk of mortality, while lower flow or area were not independently predictive. When considering different subtypes of AS, LF-LG AS had a more than twofold risk of mortality (HR 2,44 [1, 3–4, 42], p < 0,003) compared to HG. Out of the comorbidities, only patients with severe renal insufficiency (GFR < 30ml/min), or with moderate and
severe paravalvular aortic regurgitation (AR) had higher risk of mortality, besides of advanced (80+) age. The hazard ratios are demonstrated on Table 4.
### Table 4
Hazard Ratios of 1-year mortality

|                  | Hazard Ratio | CI 95%       | p   |
|------------------|--------------|--------------|-----|
| **Flow**         |              |              |     |
| < 25 ml/m²       | 1.30         | 0.74 – 2.28  | 0.35|

With the analysis of the interdependence of different echocardiographic parameters there was a moderate and positive correlation between ejection fraction and flow (R = 0,541, p < 0,0001), EF and gradient (R = 0,485, p < 0,0001), flow and area (R = 0,495, p < 0,0001), and an inverse but moderate correlation between area and gradient (R = 0,454, p < 0,0001), but the correlation of flow and gradient was weak (R = 0,206, p < 0,0001). These correlations are demonstrated on Fig. 5.

Hemodynamic parameters after TAVI

Of 249 patients who survived the first year after TAVI 199 (79,8%) underwent echocardiographic control at 1-year follow-up. The mean aortic gradient decreased (baseline 51,3+/−16,7 mmHg vs. 8,7+/−3,6 mmHg p
< 0.0001), the aortic valve area increased (baseline 0.54 +/- 0.1 cm² vs. 1.65 +/- 0.27 cm² p < 0.0001). The LVEF slightly improved in HG and LF-LG groups, but remained unchanged in PLF-GL and NF-LG groups. Changes in LVEF are provided in Fig. 6.

On the other hand, when classifying our patients solely by their initial EF, a clinically relevant and statistically significant improvement of EF could have been demonstrated in every ten-percent cluster under EF 60%, as demonstrated on Fig. 7.

**Discussion:**

Patients with LF-LG AS represent a challenging subpopulation with a poor prognosis when undergoing conservative or surgical treatment. TAVI is an alternative option, however, due to controversial data, the outcomes of TAVI and predictors of late mortality have not been clarified yet [24]. Different risk algorithms were suggested for risk stratification based on clinical and laboratory findings and LVEF, but none of them used Gr or SVI for risk stratification [13-14]. Since it is still uncertain whether these patients benefit from less invasive treatment, we aimed to evaluate the prognostic impact of different SVI-gradient AS patterns after TAVI. The main finding is that 30-day, 1-year and 3-year all-cause mortality was the highest in the LF-LG group. Our 1-year mortality results are comparable to larger registries [25,26]. The 30-day and 1-year mortality rate of the LF-LG subgroup was about 2–3 times higher than in the HG AS patients.

Reduced LVEF was found to be a predictive factor of 30-day and 1-year mortality after TAVI in several studies, [26,27]. In a recent meta-analysis of 6898 TAVI patients low SVI, low gradient, and low EF were each associated with higher mortality after TAVI [28].

In our study the PLF-LG group represented only 3.0% of the whole patient population. The 1-year mortality was worse than in patients with HG AS, but better than in the LF-LG group. The small number of PLF-LG patients and endpoints in this group doesn't allow us to draw further conclusions. The NF-LG group was heterogenous by left ventricular dimensions, with moderate LV dysfunction, but had the most favorable outcomes, similarly with previous studies [9]. For this subtype of AS, there is no recommendation for intervention, nevertheless these patients may also have better outcomes with intervention [10]. In surviving patients with initial LV dysfunction, the LVEF significantly improved 1 year after TAVI. This observation corresponds with several previous studies [24,26,27].

A relatively large proportion (59%) of our patients had low flow. The high prevalence of LF in the AS population is the consequence of frequent comorbidities and associated complications such as hypertrophy, diastolic dysfunction, ventricular dyssynchrony, impaired longitudinal function. Nevertheless, there are well-known inherent inconsistencies of the AS severity criteria in the guidelines.

We could not demonstrate the negative effect of low SVI, which is not surprising considering the high percentage (53.6%) of low flow condition in the HG group, in which the prognosis was better. On the other hand, we found moderately strong correlation between EF and flow, EF and gradient, flow and area and...
between area and gradient, so these parameters must not be emphasized solely. Beyond that, HG or LF-LG criteria were useful in the prediction of outcome. Our results correspond with one previous study in which AS subtype independently influenced long-term mortality, whereas EF, flow or low gradient alone did not [29].

In our study only moderate or severe paravalvular AR, and severe renal insufficiency were independent predictors of 1-year mortality. This finding is consistent with the results of larger registries [20,30].

Limitations:

The main limitation of our study is the relatively smaller sample size, and its single-center character. We could not estimate the risk of the PLF-LG AS, since this subgroup was small, and only 3 of them reached primary endpoint at 1-year. Despite prospective data collection, the analysis was retrospective and therefore subject to the limitations of an observational study. Besides limitations, the strenghts of our study are the complete analysis of consecutive patients, the 100% mortality tracking, and the long follow-up period up to 115 months.

Conclusions:

Our study demonstrates the impact of different subtypes of AS on outcome after TAVI. All-cause mortality was lowest in patients with HG AS, it was intermediate in patients with PLF-LG AS and highest in patients with LF-LG AS. The classification of patients into flow–gradient pattern might be useful for risk stratification before TAVI. Considering the high 1-year all-cause mortality in patients with LF-LG AS, a careful selection is warranted. In patients with LF-LG AS closer follow-up and active medical treatment of left ventricular dysfunction is needed after TAVI, in order to improve survival. Improvement of initial left ventricular dysfunction can be expected after TAVI regardless of its severity.

Declarations

Funding: None

Conflicts of interest: The authors declare that they have no conflict of interest.

Ethics approval All procedures performed in studies involving human participants were in accordance with the ethical standards of the Institutional Ethics Committee and with the 1964 Helsinki Declaration and its later amendments. Ethical approval was waived by the local Ethics Committee in view of the retrospective nature of the study and all the procedures being performed were part of the routine care.

Consent to participate: All patients provided written informed consent

Consent for publication Not applicable

Availability of data and material Not applicable
Code availability
